There are many wonderful sources, too numerous to mention here, on probability and inference, in addition to those already cited. von Mises [23] attempts to establish a mathematical foundation for frequency probability with infinite sequences or “collectives”. Classical texts on mathematical probability are those by Feller [24, 25] and Breiman [26]. References [27, 28] are standard introductions to frequentist statistical inference. The books by Jeffreys [29] and de Finetti [30, 31] are landmark texts for subjective Bayesian probability. Kyburg *et al.* [32] provide a collection of historical, influential articles on subjective probability. Fishburn [33] provides a brief overview of the axioms of subjective probability. Early texts on Bayesian inference are by Box *et al.* [34], DeGroot [35], Ferguson [36], and Zellner [37]. For theoretically inclined readers, two of the finest, modern texts on Bayesian inference are by Berger [38] and Bernardo *et al.* [39], and the work of Gelman *et al.* [40] and Congdon [41] should appeal to applied researchers. Cowell

et al. [42] and Jensen [43] provide good introductions to Bayes nets.

The internet holds a wealth of material. In particular, Hájek [44] provides a scholarly account, and Fonseca [45] summarizes the axioms of rationality. Lenk [46] provides mathematical notes on Bayesian inference using Markov chain Monte Carlo. Free statistical software, mostly frequentist, but also

Bayesian, is available through <http://www.r-project.org/>; free Bayesian software can be obtained at <http://www.mrc-bsu.cam.ac.uk/bugs/>, where one can also join an online community of Bayesians.

PETER LENK

Kriging

Kriging is the name given to a collection of spatial interpolation methods that are derived from model-based optimality criteria and provides model-based estimates of interpolation error. Kriging, as is usually practiced, proceeds in two stages. In the first stage the available spatial data are used to fit a model of spatial correlation; in the second stage the fitted model is used to optimize the interpolator and to provide error estimates. The spatial variables may be continuous spatial properties such as temperature, multivariate properties such as composition, or discrete properties such as land use. The spatial domains are typically continuous two-dimensional or three-dimensional geographic regions, but could include domains on other spatial scales, such as rock thin sections or human cells and organ scans. Kriging has been generalized to space–time interpolation problems. The data used for modeling spatial dependence and for local interpolation control are commonly measurements made at discrete locations within the spatial domain of interest, such as the data provided by a survey, by monitoring networks, and by probes of various kinds.

In its simplest form, a kriging interpolator is an optimized linear combination of control data at observation locations. The coefficients of the linear kriging interpolator and the associated error measure both depend on the spatial configuration of the control data relative to the interpolation location, as well as the fitted model of spatial correlation.

Kriging is named after D. Krige whose early interest in issues of spatial scale in mining applications [1] provided the stimulus. The kriging method has close links to Wiener optimal linear filtering in the theory of random functions, Gandin objective analysis in meteorology [2], spatial splines, and generalized least-squares estimation in a spatial context. Kriging methods have been studied and applied extensively since 1970 and have since been adapted, extended, and generalized. For example, kriging has been generalized to classes of nonlinear functions of the observations, modified to increase robustness, extended to take advantage of covariate information, adapted for fields whose statistical properties are spatially evolving, and placed into a formal Bayesian framework (*see Bayesian Statistics in Quantitative Risk Assessment*).

Matheron [3] presented an influential early systematic exposition of kriging. Among book length accounts published in the decade or so since 1990 are, in order of date, Cressie [4], Kitanidis [5], Goovaerts [6], Wackernagel [7], Armstrong [8], Olea [9], Stein [10], and Chiles and Delfiner [11]. In addition, commercial and public domain software to implement kriging is widespread and includes components written for the public domain statistical programming language R.

Model-Based Interpolation Errors

Kriging interpolators are optimized linear combinations of the control data used for interpolation. Kriging interpolators minimize the “expected” squared interpolation error computed in the context of a specified probabilistic model for the spatial field of interest, which is here called the *a priori probability model*, and the expected squared interpolation error under the *a priori* model is called the *performance* of the interpolator. The optimization under the *a priori* model does not involve conditioning on the available data, and the performance measure treats data at observed locations as though they were still random variables.

The optimization of interpolator performance, subject to unbiasedness constraints described below, yields the kriging coefficients that are applied to the control data for interpolation. These optimized coefficients depend only on the *a priori* model’s covariances between values of the spatial field at location pairs. The optimized interpolating coefficients do not depend on the actual values of the data, except insofar as the data are used to estimate the *a priori* model’s pairwise covariances.

In general, linear kriging interpolators, i.e., those that are optimized for the *a priori* model, will on average have larger squared errors than nonlinear interpolators that minimize the *conditional* expected squared error, given the available data. The advantage of kriging interpolators is that the expected squared error depends on the model only through the *a priori* covariances between values at different spatial locations, thus requiring a rather minimal model specification. In contrast, conditional expected value interpolators depend on the *a priori* model in more complicated ways that require complete model specifications.

However, when the *a priori* model is a Gaussian spatial field then the expected squared interpolation error in the kriging context coincides with the expected squared error conditioned on the data. Furthermore, the kriging interpolator will coincide with the conditional expected value at the interpolation location given the data, in this special case.

Kriging interpolation procedures are optimized pointwise, i.e., interpolation performance is separately optimized at each interpolation location. No constraints are placed on the collective properties of interpolated values and the performance measure does not consider the collective properties of interpolated values. Indeed, pointwise kriging optimization results in an interpolated spatial field whose spatial properties are not consistent with the *a priori* spatial probability model. Interpolated fields have less spatial variability and show a stronger spatial continuity than what is implied by the *a priori* model. Therefore, it is inappropriate to use a map of interpolated values obtained by kriging to infer variability or continuity properties of the spatial field.

Notation and Data

$Z(x)$ denotes the property (value) of the spatial field at location x , where x is any point (site, location) in the geographic region of interest. For example, $Z(x)$ is the surface concentration of a pollutant at location x in a specified air basin. We may generalize the spatial property $Z(x)$ to be multivariate, such as a suite of multiple-pollutant concentrations and weather variables, defined at every site x in the air basin.

$Z_0 = Z(x_0)$ is the unknown value of the spatial field at an interpolation location x_0 .

$x_i, i = 1 \dots n$, denotes n discrete data locations used for interpolating at location x_0 . These are called *the control data locations*. Control data locations are usually chosen in a neighborhood of the interpolation location x_0 .

$\mathbf{Z}_n$ is the vector of control data, i.e., the n vector of observations $Z(x_1) \dots Z(x_n)$.

Observations are not always in the form of discrete point observations. Measuring devices may produce locally averaged values, typical of remote sensing data. Or data may be measured continuously along one-dimensional trajectories such as data from moving tracking devices. Kriging methods can be generalized to accommodate such data.

The probabilistic model treats the spatial field $Z(x)$ as a random spatial function. The control data $\mathbf{Z}_n$ and the unobserved values of the field Z_0 will have a joint probability distribution that is derived from the model specification. The notation for model quantities is:

$\mu(x)$ is the *a priori* model expected value of the random variable $Z(x)$ at a location x . $\boldsymbol{\mu}_n$ is the n vector, $\mu(x_i), i = 1 \dots n$, of expected values at the n control data locations. μ_0 is the expected value, $\mu(x_0)$, at the unobserved interpolation location x_0 .

$c(x, x')$ is the model covariance between the pair of random variables $Z(x)$ and $Z(x')$ at the location pair x and x' . $\mathbf{c}_n$ is the $n \times n$ matrix, $(c(x_i, x_j))$, of variances and covariances between pairs of random variables at data locations x_i and x_j . $\mathbf{c}_0$ is the n vector of model covariances, $(c(x_i, x_0))$, between the random variable $Z(x_0)$ at the interpolation location x_0 and the random variables $Z(x_i)$ at each of the n observed locations, and $c_{0,0}$ is the model variance for the random variable at the unobserved location x_0 .

The model variogram, $\gamma(x, x')$, is defined as the expected value of the squared difference between the pair of residuals $Z(x) - \mu(x)$ and $Z(x') - \mu(x')$ for locations x and x' . The variogram may be expressed in terms of the model covariances: $\gamma(x, x') = c(x, x) + c(x', x') - 2c(x, x')$, but the variogram is usually easier to estimate directly from the available data than is the covariance function. $\boldsymbol{\gamma}_n$ is the $n \times n$ variogram matrix whose components are the variogram values for pairs of observed control locations. $\boldsymbol{\gamma}_0$ is the n vector whose components are the variogram values for the data locations paired with the interpolation location x_0 .

The Spatial Mean Function and Kriging with Unbiasedness Constraints

A linear kriging estimator, denoted Z_0^* , interpolates the value of the spatial field at an unobserved site x_0 using a linear combination of the control data values $\mathbf{Z}_n$. We write $Z_0^* = \mathbf{Z}_n' \boldsymbol{\lambda}_{n,0}$ where $\boldsymbol{\lambda}_{n,0}$ is an n vector of coefficients that multiply the values at the control locations. The notation emphasizes that kriging coefficients depend on the estimation location x_0 . The coefficients $\boldsymbol{\lambda}_{n,0}$ are chosen to minimize the expected value of the squared interpolation error $(Z_0^* - Z_0)^2$, under the *a priori* probability model.

The minimizing coefficients $\boldsymbol{\lambda}_{n,0}$ are constrained so that the interpolator is “unbiased”. Unbiasedness,

as used here, requires that the unknown Z_0 has the same expected value under the probability model as does the kriging interpolator, Z_0^* , derived from the control data $\mathbf{Z}_n$. Thus, this unbiasedness requirement regards the control data as n random variables, irrespective of their observed values. This unbiasedness constraint for kriging depends only on the *a priori*-modeled mean function, $\mu(x)$, expressed as a function of location x . The constraints on the kriging coefficients are thus given by $\mu_0 = \boldsymbol{\mu}_n' \boldsymbol{\lambda}_{n,0}$.

If the mean function $\mu(x)$ of the *a priori* spatial model is completely specified for every location x , then the *a priori* model can be reduced to a zero-mean model, i.e., we use kriging to interpolate the zero-mean residuals after subtracting the specified mean function. Then $\mu(x)$ is redefined to be zero everywhere for kriging purposes. This is called *simple kriging*. The unbiasedness constraint is trivially satisfied for simple kriging, i.e., there is no effective constraint on the kriging coefficients.

When the mean function $\mu(x)$ of the *a priori* spatial model is not completely specified then kriging typically uses a parameterized mean function that is linear in the unspecified parameters: the *a priori* mean at location x is an unspecified linear combination of “covariates” that are specified at every location x . We can write $\mu(x) = \mathbf{b}'\mathbf{f}(x)$, where $\mathbf{b}$ is an unspecified p vector consisting of mean function parameters, and $\mathbf{f}(x)$ is a specified p vector of covariate values. For example, a covariate might be the known elevation above sea level at every location, or it might simply be the latitude at location x that reflects a north–south linear trend in the mean function.

Set $\mathbf{f}_0 = \mathbf{f}(x_0)$ as the p vector of specified covariate values at the interpolation location x_0 , and $\mathbf{f}_n$ as the specified $p \times n$ matrix of covariate values at the n data locations. This parameterization of the mean function implies that the unbiasedness constraint for kriging is equivalent to $\mathbf{f}_0 = \mathbf{f}_n' \boldsymbol{\lambda}_{n,0}$. This relation represents p separate linear constraints on the kriging coefficients $\boldsymbol{\lambda}_{n,0}$. Optimized linear estimation with this kind of parametric mean function and unbiasedness constraint has been called *universal kriging*. Unbiased universal kriging does not require explicit estimation of the *a priori* mean function parameter vector $\mathbf{b}$, nor is this the goal; the goal remains interpolation of the spatial field $Z(x)$ at unobserved locations.

The unbiasedness constraints on the kriging coefficients involve covariate values only within the control data neighborhood of the interpolation location. Indeed, the implicit unspecified spatial mean parameter, $\mathbf{b}$, can in principle be different in different regions of the spatial domain, thus the spatial mean function viewed over the whole spatial domain becomes effectively nonparametric and possibly quite complex.

The simplest case is a single parameter mean, $p = 1$, with the scalar covariate $f(x)$ having the same value at all observed and unobserved locations x in the estimation neighborhood. This is a mean-stationary *a priori* model. Without loss of generality we can take $f(x) = 1$ and the scalar parameter becomes the unspecified common mean value. It follows that the unbiasedness constraint on the kriging interpolation coefficients is that their sum is unity. Optimized linear kriging estimation in the context of an unspecified constant-mean *a priori* model is called *ordinary kriging*. More general parametric mean functions with $p > 1$ typically include the constant covariate $f(x) = 1$, so that the unit sum of kriging coefficients remains one of the constraints. This inclusion simplifies expressions of the kriging performance measure. For spatial mean functions that are completely specified *a priori*, i.e., the simple kriging situation with a zero-mean function described above, there are no kriging coefficient constraints, including the unit sum constraint.

Commonly, geographic coordinates are themselves used as spatial covariates for the *a priori* spatial mean function specification like for example, a locally linear function of the spatial coordinates. For a two-dimensional region, the spatial mean is then described by an unspecified planar surface over the neighborhood that includes the unobserved interpolation location and the associated observed control locations. The local planar mean surface would vary as we vary the interpolation location and its associated control data locations, creating the potential for mean functions that are globally complex.

Imposing an unbiasedness constraint on the kriging interpolator necessarily degrades its performance, if only modestly. On the other hand, the constraint has the advantage that the expected squared error performance measure is free of the unspecified parameters of the *a priori* model spatial mean function and these

unspecified model mean parameters do not enter into the kriging interpolator optimization.

Optimization of Kriging Interpolation Coefficients

The kriging interpolation coefficients $\lambda_{n,0}$ optimize the performance measure, i.e., they minimize the *a priori* model expected value of the squared interpolation error, subject to the unbiasedness constraints on the kriging coefficients. Because of the unbiasedness constraints, minimization of expected squared error is equivalent to minimization of the error variance. In the case where there is a unit sum constraint on the kriging coefficients the error variance can be expressed in terms of the *a priori* model variogram, viz.,

$$\text{Var}\{Z_0^* - Z_0\} = 2\lambda_{n,0}'\gamma_0 - \lambda_{n,0}'\gamma_n\lambda_{n,0} \quad (1)$$

The n components of the vector γ_0 are the respective expected squared differences between the values at the n control data locations and the interpolation location, as derived from the *a priori* model variogram described earlier. The entries of the $n \times n$ matrix γ_n are likewise obtained from the variogram for the control data location pairs. Model error estimation variance involves the variogram function only for interpoint separations on the neighborhood scale of the control data locations.

The optimized kriging interpolation coefficients reflect the geometry of the control data locations in relation to the interpolation location x_0 . Typically, data closer to x_0 will have larger coefficients. Data that occur in spatial clusters will tend to each have smaller coefficients reflecting their redundancy because of their proximity, thus kriging is said to decluster data. Kriging coefficients can be negative.

The parameterization of the *a priori* model mean, as a function of spatial location, has two important implications. First, the parameterized mean function constrains the permissible unbiased interpolators. Second, the specification of the spatial mean function influences the spatial variogram. Roughly, a more complex mean function will imply that the spatial field has smaller residuals, hence a smaller variogram. The effect of a more complex mean parameterization on kriging interpolation errors is not always clear: smaller errors are associated with a smaller variogram, but larger errors are associated with more

restrictive unbiasedness constraints that accompany a more complex spatial mean parameterization.

Modeling Spatial Variograms

The performance of the unbiased linear kriging interpolator can be expressed in terms of the *a priori* variogram model that gives the expected squared difference between values of the spatial residual field at every pair of spatial locations. Typically, the variogram model is selected from a parametric class of models that are necessarily negative definite. In kriging practice, estimated parameters of the variogram model are treated as though they are specified, unlike the case of a parametric spatial mean function.

For example, the variogram may be specified as a function of the geographic vector separation between spatial locations. In this case the model is said to be second-order stationary, i.e., invariant to geographic shifting of a location pair. Further, if the variogram model depends on the geographic separation only through geographic distance, then the variogram model is said to be isotropic, i.e., invariant to geographic rotation. An example is a variogram of the form $v_1 + v_2(1 - c^d)$, where d is geographic distance between location pairs and v_1, v_2, c are positive-valued parameters with $c < 1$. This variogram model is typical in that it increases with increasing separation toward an asymptote.

Stationarity implies that, on average, residual variability is the same in all parts of the spatial field of interest. In particular, model-calculated kriging interpolation performance will depend only on the relative spatial configuration of the control data locations with respect to the interpolation location, but not on where this configuration occurs in the region of interest, nor on the observed values at the control data locations. Stationarity is imposed mainly as a model of convenience because it gives a compact variogram model, that is, a function only of separation and makes it convenient to estimate adjustable variogram parameters from the observed data. On the other hand, nonstationary variogram models could be used to assign lower kriging interpolation error variance in those parts of the region that have less spatial variability and/or greater spatial continuity.

Parameters of a parametric spatial covariance or variogram model are typically inferred from the

available field observations. If the spatial field is considered to have a constant-mean function then a plot of squared differences between data values as a function of their spatial separation can form the basis of variogram parameter estimation. A better approach is to use squared linear *contrasts* of the observations for this purpose. A contrast is a linear combination of the observations having zero expected value under the assumed spatial mean model. If there are n observation locations and p linear constraints on the mean function, then there will be $n - p$ linearly independent contrasts that can be used for variogram estimation. These linear contrasts form the basis of residual maximum-likelihood (REML) approaches to variogram estimation for Gaussian spatial models as reported by Kitanidis [5].

The variogram needs to be specified only for spatial lags that are on scales comparable to the separation among local control data values used for interpolation. For this reason, estimation of variogram models should focus on the appropriate spatial scale and should use data contrasts for estimation that involve data locations with comparable separation.

Model-derived error variances for kriging interpolators are typically computed from the fitted variogram model, treating the fitted model as though it were known. However, the fitted variogram parameters actually depend on the available data so that the model interpolation error variance, computed from the fitted variogram, is itself a data-dependent estimate of the interpolation error variance. The statistical properties of the interpolation error variance estimate require a more complete specification of the random field model.

Nugget Effect and Measurement Error

Models for spatial variograms can have different spatial scales. The short scale is smaller than the separation between data locations. The intermediate scale is that comparable to the separation among control data locations used for interpolation, called *the neighborhood scale*. The third scale is a regional scale comparable to separation between nonproximate observations. Short-scale variability is commonly inferred by extrapolation of neighborhood scale variability, although a better method is to have the sampling design incorporate closely spaced observations. When extrapolation of variograms to

short separations suggests a discontinuity at zero separation, this discontinuity is called *the nugget effect*. The nugget effect is a contribution to variability without spatial continuity. Parametric variogram models commonly include a parameter for the discontinuity at zero separation.

Measurement error, if appreciable, can be regarded as a spatial field superposed on the underlying field of interest. Then the data at the observed locations include the contributions of measurement error. Frequently, measurement errors are taken to be spatially uncorrelated on all spatial scales. In this case, the measurement error variance acts statistically like an addition to the short-scale nugget effect of the underlying field. Both the nugget effect and the zero-mean measurement error have no effect on unbiasedness constraints for kriging coefficients. However, these short-scale contributions to spatial variability can substantially affect the optimization of kriging coefficients and the model-based performance of interpolators, including kriging interpolators. For example, the optimized interpolator coefficients associated with the control data become more nearly equal and less dependent on their proximity to the interpolation location when the nugget effect is larger. The separation of the nugget effect into short-scale variability and measurement error plays no role in optimizing the kriging interpolator, although the model-computed interpolation error variance will be too large without such separation.

Cokriging and Multivariate Spatial Estimation

A spatial field is a multivariate field if, at each location x , $\mathbf{Z}(x)$ is a vector of attributes. For example, $\mathbf{Z}(x)$ could be a suite of pollutant concentrations, surface temperature, humidity, and wind speed. One might consider each of these spatial attributes as a separate field with separate modeling as described above. However, interpolation of ozone concentration, say, could have a smaller error variance if the available ozone data were supplemented by the available surface air temperature data. The ozone interpolator can be a linear function of both the ozone data and the temperature data at the control locations. The control data locations for the two variables need not be the same; indeed, temperature data may be more widely available, even at the ozone interpolation location (see **Air Pollution Risk**).

Table 1 Optimized kriging weights and interpolation errors for five variogram models

				$r = 0.1$			$r = 0.4$		$r = 0.8$
				$v = 10\%$	$v = 50\%$		$v = 10\%$	$v = 50\%$	$v = 10\%$
+	+	+	+	inner wt	18%	15%	24%	13%	21%
				outer wt	4%	5%	1%	6%	2%
+	+	+	+	E	0.95	0.97	0.71	0.79	0.43
				E^*	0.79	0.89	0.57	0.77	0.38

The expected squared error of the interpolator is now computed under an *a priori* model that expresses the joint statistical properties of both attributes. There will be model unbiasedness constraints for both the ozone and temperature coefficients. Such constrained optimized linear interpolation is called *cokriging*. For each of the variables, unbiasedness constraints will depend on the specified *a priori* spatial mean structures. For example, if each variable is assigned a common *a priori* mean value at all control data locations and the interpolation location, then unbiasedness constrains the coefficients that multiply the ozone observations to sum to unity, and the coefficients that multiply the covariate temperature observations to sum to zero. The optimization of the linear cokriging estimate requires modeling of the cross-covariance between variable pairs at location pairs.

If only the ozone randomness figures in the *a priori* probability model, while the covariate temperature information is considered fixed, then the optimization and coefficient constraints are different. For example, suppose that the mean ozone at location x , conditional on the covariate field, is taken to be an unspecified linear function of the temperature covariate at location x . Then we are in the universal kriging modeling situation described above. With this approach there is no need to model cross-covariances of ozone and temperature.

Illustration

The illustration is based on gridded data that are typical of reconnaissance surveys and satellite measurements. For definiteness suppose that radioactivity is measured at the grid locations and that we wish to quantify the uncertainty associated with kriging interpolation of the data to unmeasured locations. A variogram model, fit to the data, expresses

how radioactivity differences at two locations are related, on average, to their spatial separation d . This illustration uses a variogram model that is proportional to $2v + 2(1 - v)(1 - c^d)$, where v is the nugget variance (measurement error and short-scale variability) as a proportion of the total variance, and $r = (1 - v)c$ is the correlation between measurements at adjacent grid locations. The root-mean-squared interpolation error E is computed under the specified variogram model.

Suppose one interpolates the center of a measurement grid square using the 12 nearest measurements as control data for interpolation, as shown in Table 1, comprising an inner ring of four control data values and an outer ring of eight control data values.

Table 1 shows the following: the approximate optimized kriging weights assigned to inner-ring data values and outer-ring data values, respectively; the corresponding relative values of the model-based interpolation error E ; the reduced error E^* that would result from a fourfold increase in data density with half the original grid spacing. Five model scenarios are described with different levels of short-scale variability and correlation as represented by the variogram parameters v and r described above.

Large Insurance Losses Distributions

Subexponential Distribution Functions

Subexponential distribution functions (DFs) are a special class of heavy-tailed DFs. The name arises from one of their properties, that their right tail decreases more slowly than any exponential tail; see equation (3). This implies that large values can occur in a sample with nonnegligible probability, which proposes the subexponential DFs as natural candidates for situations where extremely large values occur in a sample compared to the mean size of the data. Such a pattern is often seen in insurance data, for instance in fire, wind–storm, or flood insurance (collectively known as *catastrophe insurance*), and also in financial and environmental data. Subexponential claims can account for large fluctuations in the risk process of a company. Moreover, the subexponential concept has just the right level of generality for risk measurement in insurance and finance models. Various review papers have appeared on subexponentials; see e.g., [1–3]; textbook accounts are in [4–8]. We present two defining properties of subexponential DFs.

Definition 1 (Subexponential distribution functions) Let $(X_i)_{i \in \mathbb{N}}$ be i.i.d. positive random variables with DF F such that $F(x) < 1$ for all $x > 0$. Denote by $\bar{F}(x) = 1 - F(x)$ for $x \geq 0$, the tail of F , and for $n \in \mathbb{N}$,

$$\begin{aligned} \bar{F}^{n*}(x) &= 1 - F^{n*}(x) \\ &= \mathbb{P}(X_1 + \dots + X_n > x), \quad x \geq 0 \end{aligned} \quad (1)$$

the tail of the n -fold convolution of F . F is a *subexponential DF* ($F \in \mathcal{S}$) if one of the following equivalent conditions holds:

- (a) $\lim_{x \rightarrow \infty} \frac{\bar{F}^{n*}(x)}{\bar{F}(x)} = n$ for some (all) $n \geq 2$
- (b) $\lim_{x \rightarrow \infty} \frac{\mathbb{P}(X_1 + \dots + X_n > x)}{\mathbb{P}(\max(X_1, \dots, X_n) > x)} = 1$ for some (all) $n \geq 2$

Remark 1 (a) A proof of the equivalence is based on ($\sim$ means that the quotient of the left hand side

and the right hand side tends to 1 as $x \rightarrow \infty$)

$$\begin{aligned} \frac{\mathbb{P}(X_1 + \dots + X_n > x)}{\mathbb{P}(\max(X_1, \dots, X_n) > x)} &\sim \frac{\bar{F}^{n*}(x)}{n\bar{F}(x)} \xrightarrow{x \rightarrow \infty} 1 \\ &\iff F \in \mathcal{S} \end{aligned} \quad (2)$$

(b) In much of the present discussion, we deal only with the right tail of a DF. This concept can be formalized by denoting two DFs F and G with support unbounded to the right *tail-equivalent* (see **Premium Calculation and Insurance Pricing; Risk Measures and Economic Capital for (Re-)insurers**) if $\lim_{x \rightarrow \infty} \bar{F}(x)/\bar{G}(x) = c \in (0, \infty)$. From Definition 1 and the fact that $\mathcal{S}$ is closed with respect to tail-equivalence, it follows that $\mathcal{S}$ is closed with respect to taking sums and maxima of i.i.d. random variables. Subexponential DFs can also be defined on $\mathbb{R}$ by requiring that F restricted to $(0, \infty)$ is subexponential; see [9–11].

(c) The heavy-tailedness of $F \in \mathcal{S}$ is demonstrated by the implications

$$\begin{aligned} F \in \mathcal{S} &\implies \lim_{x \rightarrow \infty} \frac{\bar{F}(x-y)}{\bar{F}(x)} = 1 \quad \forall y \in \mathbb{R} \\ &\implies \frac{\bar{F}(x)}{e^{-\varepsilon x}} \xrightarrow{x \rightarrow \infty} \infty \quad \forall \varepsilon > 0 \end{aligned} \quad (3)$$

A famous subclass of $\mathcal{S}$ is the class of DFs with regularly varying tails; see [12, 13].

Example 1 (Distribution functions with regularly varying tails) For a positive measurable function f we write $f \in \mathcal{R}(\alpha)$ for $\alpha \in \mathbb{R}$ (f is *regularly varying with index* α) if

$$\lim_{x \rightarrow \infty} \frac{f(tx)}{f(x)} = t^\alpha \quad \forall t > 0 \quad (4)$$

Let $\bar{F} \in \mathcal{R}(-\alpha)$ for $\alpha > 0$, then it has the representation

$$\bar{F}(x) = x^{-\alpha} \ell(x), \quad x > 0 \quad (5)$$

for some $\ell \in \mathcal{R}(0)$. To check Definition 1(a) for $n = 2$, split the convolution integral and use partial integration to obtain

$$\begin{aligned} \frac{\bar{F}^{2*}(x)}{\bar{F}(x)} &= 2 \int_0^{x/2} \frac{\bar{F}(x-y)}{\bar{F}(x)} dF(y) + \frac{(\bar{F}(x/2))^2}{\bar{F}(x)}, \\ &\quad x > 0 \end{aligned} \quad (6)$$

Immediately, by equation (4), the last term tends to 0. The integrand satisfies $\bar{F}(x-y)/\bar{F}(x) \leq \bar{F}(x/2)/\bar{F}(x)$ for $0 \leq y \leq x/2$; hence, Lebesgue dominated convergence applies and, since F satisfies equation (3), the integral on the right hand side tends to 1 as $x \rightarrow \infty$. Examples of DFs with regularly varying tail include the Pareto, Burr, transformed beta (also called generalized F), log-gamma, and stable DFs (see [6]).

Example 2 (Further subexponential distributions)

Apart from the DFs in Example 1, the lognormal, the two Benktander families and the heavy-tailed Weibull (shape parameter less than 1) also belong to $\mathcal{S}$. The integrated tail DFs (see equation (11)) of all of these DFs are also in $\mathcal{S}$ provided they have a finite mean; see Table 1.2.6 in [6].

Insurance Risk Models

The Cramér–Lundberg Model

The classical insurance risk model is the *Cramér–Lundberg model* (cf. [6–8]), where the *claim times* constitute a Poisson process, i.e., the *interclaim times* $(T_n)_{n \in \mathbb{N}}$ are i.i.d. exponential random variables with parameter $\lambda > 0$. Furthermore, the claim sizes $(X_k)_{k \in \mathbb{N}}$ (independent of the claims arrival process) are i.i.d. positive random variables with DF F and $\mathbb{E}(X_1) = \mu < \infty$. The *risk process* for initial reserve $u \geq 0$ and *premium rate* $c > 0$ is defined as

$$R(t) = u + ct - \sum_{k=1}^{N(t)} X_k, \quad t \geq 0 \quad (7)$$

where (with the convention $\sum_{i=1}^0 a_i := 0$) $N(0) = 0$ and $N(t) = \sup \{k > 0 : \sum_{i=1}^k T_i \leq t\}$ for $t > 0$. We denote the *ruin time* by

$$\tau(u) = \inf \left\{ t > 0 : u + ct - \sum_{k=1}^{N(t)} X_k < 0 \right\}, \quad u \geq 0 \quad (8)$$

The *ruin probability in infinite time* (see **Asset–Liability Management for Nonlife Insurers; Longevity Risk and Life Annuities; Reinsurance; Solvency**;

Ruin Probabilities: Computational Aspects) is defined as

$$\begin{aligned} \psi(u) &= \mathbb{P}(R(t) < 0 \text{ for some } 0 \leq t < \infty \mid R(0) = u) \\ &= \mathbb{P}(\tau(u) < \infty), \quad u \geq 0 \end{aligned} \quad (9)$$

By definition of the risk process, ruin can occur only at the claim times (see also Figure 1), hence for $u \geq 0$,

$$\begin{aligned} \psi(u) &= \mathbb{P}(R(t) < 0 \text{ for some } t \geq 0 \mid R(0) = u) \\ &= \mathbb{P}\left(u + \sum_{k=1}^n (cT_k - X_k) < 0 \text{ for some } n \in \mathbb{N}\right) \end{aligned} \quad (10)$$

Provided that $\mathbb{E}(cT_1 - X_1) = c/\lambda - \mu > 0$, then $(R(t))_{t \geq 0}$ has a positive drift and hence, $R(t) \rightarrow +\infty$ a.s. as $t \rightarrow \infty$.

A ladder height analysis shows that the *integrated tail distribution function* (see **Extreme Value Theory in Finance**)

$$F_I(x) = \frac{1}{\mu} \int_0^x \bar{F}(y) dy, \quad x \geq 0 \quad (11)$$

of F is the DF of the first undershoot of $R(t) - u$ below 0, under the condition that $R(t)$ falls below u in finite time. Setting $\rho = \lambda\mu/c < 1$, the number $\tilde{N}$ of times, where $R(t)$ achieves a new local minimum in finite time plus 1, is geometrically distributed with parameter $(1 - \rho)$, i.e. $\mathbb{P}(\tilde{N} = n) = (1 - \rho)\rho^n$, $n \in \mathbb{N}_0$. As $(R(t))_{t \geq 0}$ is a Markov process, its sample path splits into i.i.d. cycles, each starting with a new

Figure 1 Sample path of a risk process in the Cramér–Lundberg model

local minimum of the risk process. Combining these findings, we obtain the following representation of the ruin probability.

Theorem 1 (Pollaczek–Khinchine formula) *Consider the risk process 7 in the Cramér–Lundberg model with $\rho = \lambda\mu/c < 1$. Let F_I be as in equation (11). Then the ruin probability is given by*

$$\psi(u) = (1 - \rho) \sum_{n=1}^{\infty} \rho^n \overline{F_I^{n*}}(u), \quad u \geq 0 \quad (12)$$

We are interested in the ruin event represented by a probabilistic description of the last cycle before ruin, i.e., the following quantities:

- $R(\tau(u))$ the level of the risk process at ruin,
- $R(\tau(u)-)$ the level of the risk process
 just before ruin,
- $\inf_{0 \leq t < \tau(u)} R(t)$ the infimum of the risk process
 before ruin

The following result is part of the quintuple law presented in [14] with references to previous work; see also Theorem 7.7 of [15]. Its proof is based on a careful ladder height analysis of the risk process.

Theorem 2 *Consider the risk process 7 in the Cramér–Lundberg model with $\rho = \lambda\mu/c < 1$. The renewal measure of the descending ladder height process of $(ct - \sum_{k=1}^{N(t)} X_k)_{t \geq 0}$ is given by*

$$V(u) = \frac{1}{c} \sum_{n=0}^{\infty} \rho^n F_I^{n*}(u), \quad u \geq 0 \quad (13)$$

where F_I is as in equation (11). Then for $x > 0$, $v \geq y$ and $y \in [0, u]$,

$$\begin{aligned} \mathbb{P}(-R(\tau(u)) \in dx, R(\tau(u)-) \in dv, \inf_{0 \leq t < \tau(u)} R(t) \in dy) \\ = \lambda F(dx + v) V(u - dy) dv \end{aligned} \quad (14)$$

The Lévy Risk Model

A natural and useful generalization of the Cramér–Lundberg model as in equation (7) is to replace

the compound Poisson process $(\sum_{k=1}^{N(t)} X_k)_{t \geq 0}$ by a general subordinator $(S(t))_{t \geq 0}$. A *subordinator* is an increasing Lévy process, i.e., it starts at 0, has independent and stationary increments, and has a.s. increasing sample paths. A subordinator can be characterized by its *Lévy–Khinchine representation* $\mathbb{E}(\exp(ivS(t))) = \exp(t\varphi(v))$ for $t \geq 0$, $v \in \mathbb{R}$ with

$$\varphi(v) = \int_{\mathbb{R}_+} (e^{ivx} - 1) v(dx) \quad (15)$$

where v is a measure on $\mathbb{R}_+ := (0, \infty)$, called *Lévy measure*, satisfying $\int_{\mathbb{R}_+} (1 \wedge |x|) v(dx) < \infty$; see the monographs [15–18] for more details on Lévy processes. The upward movement of the subordinator represents the total claim amount process, extending the compound Poisson model by modeling many small claims between more severe claims at Poisson times.

On top of this already rather general model, uncertainty in the aggregated claims and in the premium income can be modeled by a Brownian motion $(B(t))_{t \geq 0}$ giving the risk process

$$R(t) = u + ct - S(t) + \sigma B(t), \quad t \geq 0 \quad (16)$$

where u and c are as in the Cramér–Lundberg model and $\sigma \geq 0$. More general Lévy insurance models are investigated in [14, 19–21]; see also the monograph [15]. More about the Cramér–Lundberg model perturbed by a Brownian motion can be found in [22–26] and perturbed by an α -stable Lévy motion in [27, 28]. The class of Γ -subordinators with and without perturbation by a Brownian motion have been investigated in [29, 30].

In this model, the ruin time is defined as

$$\begin{aligned} \tau(u) = \inf\{t > 0 : u + ct - S(t) + \sigma B(t) < 0\}, \\ u \geq 0 \end{aligned} \quad (17)$$

and the ruin probability by $\psi(u) = \mathbb{P}(\tau(u) < \infty)$.

Again, we have to assume that $R(t) \rightarrow +\infty$ a.s. as $t \rightarrow \infty$, which is implied by $\rho := \mathbb{E}(S(1))/c < 1$, i.e., the premium income outweighs the expected total claims.

Analogously to equation (11), we define the integrated tail DF of v as

$$v_I(x) = \frac{1}{\mathbb{E}(S(1))} \int_0^x v(y, \infty) dy, \quad x \geq 0 \quad (18)$$

In the Cramér–Lundberg model, $v(y, \infty) = \lambda \bar{F}(y)$ and $\mathbb{E}(S(1)) = \lambda \mu$, hence we get back $v_I = F_I$ and $\rho = \lambda \mu / c$.

To present the results in this general setup, we also require the exponential DF

$$G(x) = 1 - \exp\left(\frac{-2cx}{\sigma^2}\right) \mathbf{1}_{\{x > 0\}}, \quad x \geq 0 \quad (19)$$

which is the DF of $(\sup_{t \geq 0} \{-ct - \sigma B(t)\})_{t \geq 0}$. Finally, we have to build convolutions of v_I with itself and with convolution powers of G . As an explaining example, we recall that

$$\begin{aligned} G * v_I(x) &= \int_0^x G(x-y) dv_I(y) \\ &= \frac{1}{\mathbb{E}(S(1))} \int_0^x G(x-y) v(y, \infty) dy \\ &\quad \text{for } x > 0 \end{aligned} \quad (20)$$

Then the ruin probability satisfies the following equation (see [19, Theorem 3.1]).

Theorem 3 (Pollaczek–Khinchine Formula) *Consider the risk process (equation (16)) in the Lévy risk model with $\rho = \mathbb{E}(S(1))/c < 1$. Let v_I be as in equation (18) and G as in equation (19). Then the ruin probability can be represented as*

$$\psi(u) = (1 - \rho) \sum_{n=1}^{\infty} \rho^n \overline{G^{(n+1)*} * v_I^{n*}}(u), \quad u \geq 0 \quad (21)$$

For this model, the result corresponding to Theorem 2 reads as follows.

Theorem 4 *Consider the risk process (equation (16)) in the Lévy risk model with $\rho = \mathbb{E}(S(1))/c < 1$. The renewal measure of the descending ladder height process of $(ct - S(t) + \sigma B(t))_{t \geq 0}$ is given by*

$$V(u) = \frac{1}{c} \sum_{n=0}^{\infty} \rho^n (G^{(n+1)*} * v_I^{n*})(u), \quad u \geq 0 \quad (22)$$

where v_I is as in equation (18) and G as in (19). Then for $x > 0$, $v \geq y$ and $y \in [0, u]$,

$$\begin{aligned} \mathbb{P}(-R(\tau(u)) \in dx, R(\tau(u)-) \in dv, \\ \inf_{0 \leq t < \tau(u)} R(t) \in dy) \\ = v(dx + v)V(u - dy) dv \end{aligned} \quad (23)$$

Risk Theory in the Presence of Heavy Tails

Asymptotic Ruin Theory

In this section we investigate the occurrence of large, possibly ruinous claims modeled by $v_I \in \mathcal{S}$, which translates in the Cramér–Lundberg model to $F_I \in \mathcal{S}$. We refer to [20, 21] for more details on the results of this section; these papers also include more general Lévy insurance risk models. The results for the Cramér–Lundberg model can also be found in [4].

The following part (a) of Proposition 1 is found in [31], Proposition 1. The result (b) can partly be found already in [5]. Its present form goes back to [31–33].

Proposition 1 (a) *Let $H = G * F$ be the convolution of two DFs on $(0, \infty)$. If $F \in \mathcal{S}$ and $\bar{G}(x) = o(\bar{F}(x))$ as $x \rightarrow \infty$, then $H \in \mathcal{S}$.*

(b) *Suppose $(p_n)_{n \geq 0}$ defines a probability measure on $\mathbb{N}_0$ such that $\sum_{n=0}^{\infty} p_n (1 + \varepsilon)^n < \infty$ for some $\varepsilon > 0$ and $p_k > 0$ for some $k \geq 2$. Let*

$$K(x) = \sum_{n=0}^{\infty} p_n H^{n*}(x), \quad x \geq 0 \quad (24)$$

Then

$$\begin{aligned} H \in \mathcal{S} &\iff \lim_{x \rightarrow \infty} \frac{\bar{K}(x)}{\bar{H}(x)} = \sum_{n=1}^{\infty} n p_n \\ &\iff K \in \mathcal{S} \quad \text{and} \quad \bar{H}(x) \neq o(\bar{K}(x)) \\ &\quad \text{as } x \rightarrow \infty \end{aligned} \quad (25)$$

For the ruin probability, this Proposition along with the Pollaczek–Khinchine formula (Theorem 3) implies the following result.

Theorem 5 (Ruin Probability) *Consider the risk process (equation (16)) in the Lévy risk model with $\rho = \mathbb{E}(S(1))/c < 1$. If $v_I \in \mathcal{S}$, then as $u \rightarrow \infty$*

$$\begin{aligned} \psi(u) &\sim \frac{\rho}{1 - \rho} \bar{v}_I(u) \\ &= \frac{1}{c - \mathbb{E}(S(1))} \int_u^{\infty} v(y, \infty) dy \end{aligned} \quad (26)$$

Sample Path Leading to Ruin

Not surprisingly, the asymptotic behavior of the quantities in Theorem 4 are consequences of extreme

value theory; see [6] or any other book on extreme value theory for background. As shown in [34], under weak regularity conditions, a subexponential DF F belongs to the *maximum domain of attraction* of an extreme value DF G_α , $\alpha \in (0, \infty]$, (we write $F \in MDA(G_\alpha)$), where

$$G_\alpha(x) = \Phi_\alpha(x) = \exp(-x^{-\alpha})\mathbf{1}_{\{x>0\}},$$

$$\text{for } \alpha < \infty \quad \text{and} \quad (27)$$

$$G_\infty(x) = \Lambda(x) = \exp(-e^{-x}) \quad (28)$$

The meaning of $F \in MDA(G_\alpha)$ is that there exist sequences of constants $a_n > 0$, $b_n \in \mathbb{R}$ such that

$$\lim_{n \rightarrow \infty} n\bar{F}(a_n x + b_n) = -\log G_\alpha(x)$$

$$\forall x \in \begin{cases} (0, \infty) & \text{if } \alpha \in (0, \infty) \\ \mathbb{R} & \text{if } \alpha = \infty \end{cases} \quad (29)$$

The following result describes the behavior of the process at ruin, and the upcrossing event itself; see [21].

Theorem 6 (Sample Path Leading to Ruin) *Consider the risk process 16 in the Lévy risk model with $\rho = \mathbb{E}(S(1))/c < 1$. Define $\tilde{v}(x) := v(1, x)/v(1, \infty)$ for $x > 1$ and assume that $\tilde{v} \in MDA(G_{\alpha+1})$ for $\alpha \in (0, \infty]$. Define $a(\cdot) = v_I(\cdot, \infty)/v(\cdot, \infty)$. Then, in $\mathbb{P}(\cdot \mid \tau(u) < \infty)$ distribution,*

$$\left(\frac{R(\tau(u)-) - u}{a(u)}, \frac{-R(\tau(u))}{a(u)} \right) \longrightarrow (V_\alpha, T_\alpha),$$

$$\text{as } u \rightarrow \infty \quad (30)$$

V_α and T_α are positive random variables with DF satisfying for $x, y > 0$

$$\mathbb{P}(V_\alpha > x, T_\alpha > y) = \begin{cases} \left(1 + \frac{x+y}{\alpha}\right)^{-\alpha} & \text{if } \alpha \in (0, \infty) \\ e^{-(x+y)} & \text{if } \alpha = \infty \end{cases} \quad (31)$$

Remark 2 Extreme value theory (see **Individual Risk Models; Extreme Value Theory in Finance; Extreme Values in Reliability; Mathematics of Risk and Reliability: A Select History; Copulas and Other Measures of Dependency**) and Theorem 4 form the basis of this result: recall first that $\tilde{v} \in MDA(\Phi_{\alpha+1})$ is equivalent to $v(\cdot, \infty) \in \mathcal{R}(-(\alpha+1))$ and, hence, to $v_I \in MDA(\Phi_\alpha)$ by Karamata's

theorem. The normalizing function $a(u)$ tends in the subexponential case to infinity as $u \rightarrow \infty$. For $v(\cdot, \infty) \in \mathcal{R}(-(\alpha+1))$ Karamata's theorem gives $a(u) \sim u/\alpha$ as $u \rightarrow \infty$.

Insurance Risk Models with Investment

The following extension of the insurance risk process has attracted attention over recent years. It is based on the simple fact that an insurance company not only deals with the risk coming from insurance claims, but also invests capital on a large scale in financial markets. To keep the level of sophistication moderate, we assume that the insurance risk process $(R(t))_{t \geq 0}$ is the Cramér–Lundberg model as defined in equation (7). We suppose that the insurance company invests its reserve into a Black–Scholes type market (see **Default Risk**) consisting of a *riskless bond* and a *risky stock* modeled by an exponential Lévy process (see **Lévy Processes in Asset Pricing**). Their price processes follow the equations

$$P_0(t) = e^{\delta t} \quad \text{and} \quad (32)$$

$$P_1(t) = e^{L(t)}, \quad t \geq 0 \quad (33)$$

The constant $\delta > 0$ is the *riskless interest rate*, $(L(t))_{t \geq 0}$ denotes a Lévy process characterized by its Lévy–Khintchine representation $\mathbb{E}(\exp(ivL(t))) = \exp(t\varphi(v))$ for $t \geq 0$, $v \in \mathbb{R}$, with

$$\varphi(v) = ivm - \frac{1}{2}v^2\sigma^2$$

$$+ \int_{\mathbb{R}} (e^{ivx} - 1 - ivx\mathbf{1}_{[-1,1]}(x)) v(dx) \quad (34)$$

The quantities (m, σ^2, ν) are called the *generating triplet* of the Lévy process L . Here, $m \in \mathbb{R}$, $\sigma^2 \geq 0$, and ν is a Lévy measure satisfying $\nu(\{0\}) = 0$ and $\int_{\mathbb{R}} (1 \wedge |x|^2) \nu(dx) < \infty$. We assume that

$$0 < \mathbb{E}(L(1)) < \infty \quad \text{and} \quad \text{either}$$

$$\sigma > 0 \quad \text{or} \quad \nu(-\infty, 0) > 0 \quad (35)$$

such that $L(t)$ is negative with positive probability and hence, $P_1(t)$ is less than one with positive probability.

We denote by $\theta \in (0, 1]$ the *investment strategy*, which is the fraction of the reserve invested into the risky asset. For details and more background on this

model, we refer to [35]. Then the *investment process* is the solution of the stochastic differential equation

$$dP_\theta(t) = P_\theta(t-) d((1 - \theta)\delta t + \theta\widehat{L}(t)), \quad t \geq 0 \quad (36)$$

where $(\widehat{L}(t))_{t \geq 0}$ is a Lévy process satisfying $\mathcal{E}(\widehat{L}(t)) = \exp(L(t))$, and $\mathcal{E}$ denotes the stochastic exponential (cf. [36]). The solution of equation (36) is given by

$$P_\theta(t) = e^{L_\theta(t)}, \quad t \geq 0 \quad (37)$$

where L_θ is such that

$$\mathcal{E}((1 - \theta)\delta t + \theta\widehat{L}(t)) = \exp(L_\theta(t)) \quad (38)$$

The *integrated risk process* of the insurance company is given by

$$I_\theta(t) = e^{L_\theta(t)} \left(u + \int_0^t e^{-L_\theta(v)} (c \, dv - dS(v)) \right), \quad t \geq 0 \quad (39)$$

In this model with L and R independent, we are interested in the ruin probability

$$\psi_\theta(u) = \mathbb{P}(I_\theta(t) < 0 \text{ for some } t \geq 0 \mid I_\theta(0) = u), \quad u \geq 0 \quad (40)$$

To find the asymptotic ruin probability for such models, there exist two approaches. The first one is analytic and derives an integro-differential equation for the ruin probability, whose asymptotic solution can, in certain cases, be found. This works in particular for the case where the investment process is a geometric Brownian motion with drift, and has been considered in [37–40]; see also [41] for an overview.

This method breaks down for general exponential Lévy investment processes. However, equation (39) can be viewed as a continuous time random recurrence equation, often called a *generalized Ornstein–Uhlenbeck process*, cf. [42] and references therein. Splitting up the integral in an appropriate way, asymptotic theory for discrete random recurrence equations can be applied. The theoretical basis for this approach can be found in [43] and is based on the seminal paper [44]. This approach is applied in [45, 46].

The common starting point is the process $(I_\theta(t))_{t \geq 0}$ as defined in equation (39), which is the same as the process (9) in [45]. We present Theorem

5 (a) of [45] below and formulate the necessary conditions in our terminology. The Laplace exponent of L_θ is denoted by $\phi_\theta(v) = \log \mathbb{E}(e^{-vL_\theta(1)})$. If we assume that

$$\mathcal{V}_\infty := \{v \geq 0 : \mathbb{E}(e^{-vL_1}) < \infty\} \text{ is right open} \quad (41)$$

then (cf. e.g., Lemma 4.1 of [35]) there exists a unique $\kappa(\theta)$ such that

$$\phi_\theta(\kappa(\theta)) = 0 \quad (42)$$

Theorem 7 (Ruin probability) *We consider the integrated risk process $(I_\theta(t))_{t \geq 0}$ as in equation (39) satisfying equations (35) and (41). Furthermore, we assume for the claim size variable X that $\mathbb{E}(X^{\kappa(\theta)+\epsilon}) < \infty$ for some $\epsilon > 0$, where $\kappa(\theta)$ is given in (42), and we assume that $\phi_\theta(2) < \infty$. Let U be uniformly distributed on $[0, 1]$ and independent of $(L_\theta(t))_{t \geq 0}$. Assume that the DF of $L_\theta(U)$ has an absolutely continuous component. Then there exists a constant $C_1 > 0$ such that*

$$\psi_\theta(u) \sim C_1 u^{-\kappa(\theta)}, \quad \text{as } u \rightarrow \infty \quad (43)$$

Remark 2 If the insurance company invests its money in a classical Black–Scholes model, where $L(t) = \gamma t + \sigma^2 W(t)$, $t \geq 0$, is a Brownian motion with drift $\gamma > 0$, variance $\sigma^2 > 0$, and $(W(t))_{t \geq 0}$ is a standard Brownian motion, then $(L_\theta(t))_{t \geq 0}$ is again a Brownian motion with drift $\gamma_\theta = \theta\gamma + (1 - \theta)(\delta + \frac{\sigma^2}{2}\theta)$ and variance $\sigma_\theta^2 = \theta^2\sigma^2$. Since

$$\phi_\theta(s) = -\gamma_\theta s + \frac{\sigma_\theta^2}{2} s^2, \quad s \geq 0 \quad (44)$$

we obtain $\kappa(\theta) = 2\gamma_\theta/\sigma_\theta^2$. Hence, if $\mathbb{E}(X^{\max\{1, \kappa(\theta)+\epsilon\}}) < \infty$ for some $\epsilon > 0$, Theorem 7 applies.

Whereas the ruin probability is indeed the classical insurance risk measure, other risk measures have been suggested for investment risk. The *discounted net loss process*

$$V_\theta(t) = \int_0^t e^{-L_\theta(v)} (dS(v) - c \, dv), \quad t \geq 0 \quad (45)$$

converges a.s. to V_θ^* when $\phi_\theta(1) < \lambda$, and measures the risk of the insurance company, since, in particular,

the relation

$$\mathbb{P}(I_\theta(t) < 0 \mid I_\theta(0) = u) = \mathbb{P}(V_\theta(t) > u),$$

$$t, u \geq 0 \quad (46)$$

holds. This fact has been exploited in [35] to review this model from the point of view of the investing risk manager. Invoking the value-at-risk as alternative risk measure to the ruin probability, the tail behavior of V_θ^* is derived. For heavy tailed as well as for light tailed claim sizes V_θ^* has right Pareto tail, indicating again the riskiness of investment. See also [47, 48] for further insight into this problem.

Acknowledgment

The paper was written when the first author visited the Department of Operations Research and Industrial Engineering at Cornell University. She takes pleasure in thanking the colleagues there for their hospitality. Financial support by the Deutsche Forschungsgemeinschaft through a research grant is gratefully acknowledged.

Latin Hypercube Sampling

Background

Latin hypercube sampling (LHS) has gained widespread use since its development by W. J. Conover of Texas Tech University in the summer of 1975 while he was serving as a consultant to Los Alamos National Laboratory. LHS has been used worldwide in such computer modeling applications as hurricane loss projection modeling in Florida [1–4]; risk assessment for geologic isolation of radioactive waste at Yucca Mountain in Nevada [5, 6] and the WIPP site in New Mexico [7–9]; and safety assessments for nuclear power plants throughout the world [10, 11]. It is also used in computer modeling for reliability analyses for manufacturing equipment, particularly in optimization schemes for repairable equipment [12]. Other applications include the petroleum industry [13]; transmission of HIV [14]; and subsurface stormflow modeling [15]. Iman and Conover [16] present a lengthy and detailed application of LHS to risk assessment. Surveys of sensitivity analysis procedures that can be used in conjunction with LHS can be found in Kleijnen and Helton [17], Helton and Davis [18], and Helton *et al.* [19]. In addition, a Google search for LHS reveals a multitude of wide ranging applications.

An overview article on LHS was given by Iman [20]. Helton and Davis [21] present 325 references for the use of LHS in the propagation of uncertainty in complex systems. Software to implement the LHS strategy was developed in 1975 by R.L. Iman. This software was refined and was first released formally in 1980 [22]. A later revision [23] has been the most widely distributed mainframe version of the program. Commercial vendors of LHS software include @RISK® and Crystal Ball®. The first journal article on LHS appeared in *Technometrics* [24].

Latin Hypercube Sampling

In the summer of 1975, Conover was asked by Los Alamos National Laboratory to develop a method for improving the efficiency of simple Monte Carlo used to characterize the uncertainty in inputs to

computer models. Conover's work (Conover [25, 26, Appendix A]) resulted in the development of a stratified Monte Carlo sampling scheme to improve on the coverage of the input space. The stratification is accomplished by dividing the vertical axis on the graph of the distribution function of a random variable X_j into n nonoverlapping intervals of equal length, where n is the number of computer runs to be made. Through the inverse function $F^{-1}(x)$, these n intervals divide the horizontal axis into n equiprobable, but not necessarily equal length, intervals. Thus, the x axis has been stratified into n equiprobable and nonoverlapping intervals. The next step in the LHS scheme requires the random selection of a value within each of the n intervals on the vertical axis. When these values are mapped through $F^{-1}(x)$, exactly one value will be selected from each of the intervals previously defined on the horizontal axis. Let $\mathbf{X}$ be an $n \times k$ matrix whose j th column contains the LHS for the random variable X_j . A random process must be used to ensure a random ordering of the values within each column of this matrix. This mixing process serves to emulate the pairing of observations in a simple Monte Carlo process.

To fully appreciate the value of the underlying structure of LHS, it is helpful to be familiar with computer models used in actual applications. Such models are usually characterized by a large number of input variables (perhaps as many as a few hundred) and usually only a handful of these inputs are important for a given response. In addition, the model response is frequently multivariate and time dependent. If the input values were based on a factorial design, each level of each factor would be repeated many times. Moreover, the experimenter usually has a particular response in mind when constructing the factorial design and this design may be totally ineffective with multiple responses. On the other hand, LHS ensures that the entire range of each input variable is completely covered without regard to which single variable or combination of variables might dominate the computer model response(s). This means that a single sample will provide useful information when some input variable(s) dominate certain responses (or certain time intervals), while other input variables dominate other responses (or time intervals). By sampling over the entire range, each variable has the opportunity to show up as important, if it is indeed important. If an input

variable is not important, then the method of sampling is of little or no concern. The efficiency of LHS relative to simple random sampling is considered by Iman [20] for a range of conditions.

Many computer models used for risk assessment and other applications require correlated input values. A technique for inducing rank correlation structures among input variables for both simple Monte Carlo and LHS was given by Iman and Conover [27]. Sallaberry *et al.* [28] consider an extension of LHS with correlated variables.

Application to Hurricane Loss Projection Methodology

Iman *et al.* [29] provide a detailed overview of problems associated with projecting losses associated with hurricanes, which is a complex and difficult undertaking that is fraught with uncertainties. Hurricane Charley, which struck southwest Florida on August 13, 2004, illustrates the uncertainty of forecasting damages from these storms. Owing to shifts in the track and the rapid intensification of the storm, real time estimates grew from \$2 to \$3 billion in losses late on the 12th, to a peak of \$50 billion for a brief time, as the storm appeared to be headed for the Tampa Bay area. The storm struck the resort areas of Charlotte Harbor and moved across the densely populated central part of the state, with early poststorm estimates in the \$28 to \$31 billion dollar range, and final estimates converging at \$15 billion as the actual intensity at landfall became apparent. The Florida Commission on Hurricane Loss Projection Methodology (FCHLPM) has a great appreciation for the role of computer models in projecting losses from

hurricanes. The FCHLPM contracts with a professional team to perform on-site (confidential) audits of computer models developed by several different companies in the United States who seek to have their models approved for use in insurance rate filings in Florida. The team's members represent the fields of actuarial science, computer science, meteorology, statistics, and wind and structural engineering. An important part of the auditing process requires uncertainty analyses (UA) and sensitivity analyses (SA) to be performed with the applicant's proprietary model. LHS is an integral part of these analyses.

The approach to both UA and SA is based on sampling the range of uncertainty associated with some key computer input variables and then using the LHS values (correlated and uncorrelated) with the computer model to produce wind speed and subsequent loss. Figure 1 shows a schematic representation of the input-output process for generating wind velocity and loss for k input variables based on an LHS of size n with outputs computed for t hours.

The goal of SA is to determine which of the k inputs in Figure 1 influence both wind velocity at time t at a given location (latitude, longitude) and cause maximum loss cost. The general goal of UA is to determine which of the k inputs contribute to the uncertainty in the same output variables at time t at a given location.

Iman *et al.* [3, 4] give a detailed SA and UA for a Holland [30] wind model, and a cubic damage function [31] is used to convert wind speed to percent damage. Those analyses are now briefly summarized.

The Holland model was used to calculate wind speed (WS) for Category 1 ($74 \leq WS < 96$ mph); Category 3 ($110 \leq WS < 130$ mph); and Category

Figure 1 Schematic representation of the input-output process for UA/SA

5 ($WS \geq 155$ mph) hurricanes. Wind speeds were calculated hourly for 12 h at each vertex in a 21×46 grid (966 vertices) that covered a portion of the path of each simulated hurricane along a $60 \text{ mi} \times 135 \text{ mi}$ area crossing southern Florida.

The following four input variables were selected for this analysis ($k = 4$ in the first box of Figure 1):

- central pressure (CP) – the barometric pressure (mb) at the center of the storm (in general, the lower the CP compared to the far field pressure, the stronger the storm in terms of wind speed);
- radius of maximum winds ($R_{\max}$) – the radius (mi) from the center of the storm to the point of maximum winds (the eye wall) surrounding the storm;
- forward speed (V_T) – speed (mph) at which the storm is moving along the earth’s surface (not the speed at which winds are circulating around the storm center);
- Holland B parameter (B) – a parameter in the wind field model that defines the shape of the wind field, and is dependent on the maximum wind speed and the difference between environmental pressure and CP as explained in the next section.

Each of these input characteristics (variables) has an associated degree of uncertainty for a specific storm, which were described by triangular distributions. CP and $R_{\max}$ are likely to have some degree of correlation or linear relationship, particularly for a Category 5 hurricane.

Standardized regression coefficients (SRC) provide a very convenient metric for presenting SA results. SRCs are easily calculated from the inverse of the simple correlation matrix for the four input variables and the wind speeds produced by the Holland wind field at a given set of grid coordinates for a fixed time and a given storm category. These can also be calculated for the maximum loss at each grid point. Iman, Johnson and Schroeder [21] provide details of the SRC calculations.

Graphical displays of SRCs are very useful in interpreting the results of the SA. Figure 2 shows how the influence of $R_{\max}$ changes over time at a fixed point in the grid as the eye of Category 1, 3, and 5 hurricanes pass this point at $t = 3$ h. Figure 3 shows how $R_{\max}$ influences the maximum wind speed over the entire $60 \text{ mi} \times 135 \text{ mi}$ grid, ranging

Figure 2 SRCs for $R_{\max}$ at a single grid point over time

Figure 3 SRCs for $R_{\max}$ for a category 5 at $t = 2$ h over the entire grid

from a negative influence inside the eye wall to a positive influence outside the eye wall.

As previously stated, the goal of uncertainty analysis is to quantify the contributions of the input variables to the uncertainty in total wind speed and maximum loss. These contributions are referred to as expected percentage reduction (EPR) in the variance of the output. There are several steps in the calculation of these contributions, which involve the processing of additional LHSs. Complete details of the calculation and an illustrated example with a simple analytic model can be found in Iman *et al.* [2]. The same reference also provides a detailed step-by-step illustration of how to estimate the EPR in

the variance of the output variable(s) based on actual computer input and output. The calculation of EPR is based on a method given by Iman [32], referred to as *uncertainty importance*.

As with SA, graphical displays are useful for conveying the results of UA. Figures 4 and 5 are the respective analogs of Figures 2 and 3. Figure 4 shows how the EPR owing to $R_{\max}$ changes over time at a fixed point in the grid as the eye of Category 1, 3, and 5 hurricanes pass this point at $t = 3$ h. Figure 3 shows how $R_{\max}$ influences the variation in the maximum wind speed over the entire $60 \text{ mi} \times 135 \text{ mi}$ grid, ranging from a small contribution inside the eye wall to a very strong contribution at and near the eye wall as one would expect.

Figure 4 EPRs for $R_{\max}$ at a single grid point over time

Figure 5 EPRs for $R_{\max}$ for a category 5 at $t = 2$ h over the entire grid

The interested reader can check out the references given in this article to gain a more complete understanding of how LHS provides for efficient and effective uses of what are frequently very time consuming computer model calculations and also sets up the subsequent uncertainty and sensitivity analyses.

RONALD L. IMAN

Lead

Background

As with all metals, there are three forms of lead: elemental, inorganic, and organic. Elemental lead is a dense, blue-gray, soft metal that occurs naturally. Its softness, ability to resist corrosion, high density, and low melting point make it useful for plumbing, solder, batteries, weights, and as a shield for radiation. The inorganic form of lead is the most common; it is mined from the earth as an ore. Among many other uses, lead was used as a pigment in paint and ceramics; it is also used in ammunition. The organic forms of lead—mainly tetraethyl and tetramethyl—were used as antiknock agents^a in gasoline, beginning in the 1920s. Most countries have since phased it out, but it is still commonly used in aviation fuel. In the past three centuries, the amount of lead in the environment has increased over 1000-fold because of human activity. However, most uses of lead are being reduced owing to the adverse health effects associated with exposure.

Purpose

This article summarizes the unique aspects of lead that must be considered during the risk assessment process and discusses the wealth of data that exists for each of the four risk assessment steps. Since the majority of exposure today is to inorganic lead, that is the emphasis of this article. Also, since there is extensive data on the effects of lead exposure in humans, we do not address animal studies. Finally, the article discusses the United States Occupational Safety and Health Administration (OSHA)'s current risk management policies.

Special Considerations

Lead has several characteristics that require careful attention in considering its human health effects. First, lead exposure patterns, toxicokinetics, and health effects differ between children and adults. Second, lead has well-validated biomarkers of exposure, which must be interpreted carefully with regard

to what they represent. This is because interpreting associations of health effects with measures of recent dose differs substantially from that of cumulative dose. More specifically, health effects associated with recent dose may be more likely to be acute and reversible, while those associated with cumulative dose may be more likely to be chronic and irreversible. Third, occupational exposures differ from environmental exposures as they are usually of higher intensity, occur over an 8-h period (*versus* a 24-h period), mainly occur in adults within a narrow age range (e.g., 18–60 years), and generally only occur in healthy persons, as unhealthy individuals are often selected out of the workplace (i.e., the healthy worker effect). Further discussion of these points follows.

Children have a greater risk of environmental exposure to lead owing to their proximity to the ground, hand-to-mouth activity, increased time outdoors, pica behavior, the sweet taste associated with lead paint, and their inability to judge risk. Additionally, per kilogram of body weight, children take in more fluids, food, and air compared to adults. Absorption of lead through the gastrointestinal tract is higher in children and it more readily crosses their blood-brain barrier [1]. Furthermore, children exhibit more severe health effects at lower doses than adults. Lead also crosses the placenta; although some of the data are mixed, children born to lead-exposed mothers may be born early, have decreased birth weight, cognitive sequelae, or birth defects.

There are two well-validated biomarkers of lead exposure: lead in whole blood and lead in bone. Other markers, used less frequently and with less supportive validation evidence, include tooth lead, urinary lead, chelatable lead (after dimercaptosuccinic acid or ethylene diamine tetraacetic acid, and hair or nail lead. Blood lead levels are the most commonly obtained estimate of dose, probably due to cost, convenience, and the fact that most occupational standards utilize it extensively. Lead has a clearance half-time of approximately 30 days from blood, and thus reflects integrated exposure from external and internal sources, over approximately 120 days; a single measurement, for example, cannot distinguish between a high-level recent exposure and lower-level long-term exposures. Serial measurements of blood lead give a better picture of lead exposure over time and their integral (i.e., area-under-the-curve of blood

lead *versus* time) correlates well with tibia lead, a measure of cumulative dose.

The characteristics of the biomarkers discussed above are important since the health effects associated with recent dose differ from those associated with cumulative dose. High-level, short-term exposures can result in lead's direct action on cellular receptors, other proteins, and calcium agonism or antagonism, leading to death, encephalopathy, cognitive dysfunction, and transient hypertension. If patients are removed from the source of exposure, some of these effects are reversible. In contrast, the chronic effects of cumulative dose are associated with more permanent changes in cellular architecture and synaptic density, leading to persistent or progressive health effects, such as chronic hypertension, cognitive decline that continues even after cessation of exposure, and increased risk of death because of cardiovascular outcomes.

Existing Risk Assessments

Several existing assessments estimate the risk of adverse health effects due to lead exposure (*see Environmental Hazard; Environmental Health Risk*). For example, in the United States, the Agency for Toxic Substances and Disease Registry (ATSDR) and the Environmental Protection Agency (EPA), as well as state governments, perform risk assessments at specific sites suspected to contain high levels of lead, such as superfund sites or homes built before the ban on lead-based paint [2–4]. Additionally, every 3 years the EPA releases an assessment of health risks from toxic air pollutants, including lead. This assessment is based on emissions, and uses models to describe ambient levels, human exposure, and risk [5]. With regard to occupational exposure, the National Institute for Occupational Safety and Health (NIOSH) performs health hazard evaluations of lead in specific workplaces, as requested [6].

Hazard Identification

Lead exposure at high doses can cause death. Although this is rarely encountered now, reports at the turn of the last century estimated hundreds of deaths per year because of childhood or occupational lead poisoning. Lead is a nonspecific toxicant and acts throughout the body, not only to antagonize

calcium, thus interfering with basic biochemical processes such as cell messaging, but also to bind with proteins, thus altering protein structure and inhibiting enzyme function. Because of this nonspecificity, lead affects many organ systems, including the neurological, cardiovascular, circulatory, gastrointestinal, hematopoietic, musculoskeletal, and renal systems. Some of the main health effects are discussed below. For all health outcomes, an increasing number of studies over the past decade have documented health effects associated with tibia lead, suggesting that lead separately causes acute health effects as a function of recent dose, and chronic health effects as a function of cumulative dose.

Neurological effects include both central nervous system and peripheral nervous system impairments. High doses of lead are associated with encephalopathy in both adults and children. In adults, central nervous system symptoms include anxiety, depression, dizziness, fatigue, forgetfulness, headache, impotence, irritability, lethargy, malaise, nervousness, and weakness. Adult neurobehavioral test results show dose–response relationships across many cognitive domains, with some of the most consistent and strongest relationships occurring on tests of manual dexterity, executive abilities, and verbal memory and learning. Peripheral nervous system symptoms include paresthesias and weakness; some authors consider lead to have a larger influence on peripheral motor function than sensory function. Testing shows impaired nerve conduction velocities and postural balance. Additionally, epidemiologic evidence exists for a link between lead exposure and development of both amyotrophic lateral sclerosis and Parkinson's disease; biochemical evidence suggests lead may interact with both amyloid and tau protein, providing a possible link to Alzheimer's disease.

In children, lead dose is consistently associated with impaired intellectual function as measured by intelligence (IQ) tests in epidemiologic studies in several countries. Central nervous system impairments include decreased attention, memory, nonverbal reasoning ability, and visual-motor performance. Peripheral neuropathy is demonstrated *via* impaired fine motor skills and decreased nerve conduction velocities. Behaviorally, lead-exposed children are more likely to display antisocial behaviors such as aggression, delinquency, and marijuana use.

Occupational epidemiological studies in adults comprise the majority of studies on renal effects

and most use blood lead levels as their biomarker, although an increasing number measure tibia lead. Lead causes well-documented and consistent adverse effects in the renal system including proximal tubular nephropathy, glomerular sclerosis, and interstitial fibrosis. Impairments in function include depressed glomerular filtration rate, enzymuria, impaired transport of organic anions and glucose, and proteinuria.

Cardiovascular effects include increased risk of mortality from cardiovascular disease, coronary heart disease, and stroke. Well-documented data from numerous epidemiologic studies, both occupational and environmental, demonstrate a consistently increased prevalence of both hypertension and peripheral arterial disease. Intermediate effects include changes in cardiac conduction or rhythm as well as changes in left ventricular function or mass. These effects have been more studied in adults, but some studies indicate that exposure in childhood might be associated with the development of hypertension in adulthood. Although most studies evaluated associations with blood lead levels, bone lead levels are increasingly recognized as a better predictor of hypertension, implying that cumulative dose is the more relevant metric.

Some epidemiological studies associate lead exposure with reproductive effects in adults. Moderately high blood lead levels appear to be linked to spontaneous abortion and premature delivery in pregnant women, while men may exhibit decreased fertility and changes in sperm. Most of these studies measured blood lead levels in occupationally exposed workers, or people living near a lead-related industry. Studies of *in utero* effects measuring lead in maternal or child blood found neurodevelopmental effects, as well as decreased height and weight gain rates.

Most studies of the relationship between lead and cancer are occupational epidemiology studies of blood lead levels (*see Occupational Cohort Studies*). Many of the studies do not control for concurrent risk factors such as smoking, arsenic exposure, or dietary habits. However, there are fairly consistent associations between high lead levels and cancer, specifically cancers of the digestive and respiratory system. EPA classifies inorganic lead as a probable human carcinogen, based on inadequate evidence in humans and sufficient evidence in animals. The US Department of Health and Human Services states that lead and lead compounds are reasonably anticipated to be human carcinogens. The International Agency

for Research on Cancer has determined that inorganic lead is probably carcinogenic to humans.

Dose–Response Relationship

For adults, cardiovascular and neurological outcomes comprise the most sensitive health endpoints associated with lead exposure. Researchers have documented acute neurological effects at blood lead levels over $20\text{ }\mu\text{g dl}^{-1}$. Recent evidence indicates that cardiovascular changes occur at even lower levels of exposure. Lead levels above $5\text{ }\mu\text{g dl}^{-1}$ are associated with increased risk of coronary heart disease, peripheral arterial disease, and elevations in blood pressure. Analyses indicate that for each doubling of blood lead levels there is a 1 mmHg increase in systolic blood pressure and a 0.6 mmHg increase in diastolic blood pressure, although there is some inconsistency in effect estimates across studies (*see Dose–Response Analysis; Threshold Models*).

In children, neurological effects are considered the most sensitive endpoint. Neurodevelopmental effects are consistently seen below $10\text{ }\mu\text{g dl}^{-1}$; most researchers agree that there is no evidence for a threshold below which adverse effects are not expected to occur. Analyses indicate that for every $1\text{ }\mu\text{g dl}^{-1}$ increase in blood lead there is an approximate decrease in IQ of 0.9 points. The relation between blood lead and IQ may not be linear; an increasing body of evidence suggests the adverse slope is steeper below $10\text{ }\mu\text{g dl}^{-1}$.

Certain factors, such as age and genetics, may make individuals more susceptible to the effects of lead exposure, giving the dose–response curve a steeper slope or shifting it to the left.

On the basis of epidemiologic evidence in 1991, and with the goal of being protective of the most sensitive subpopulation (children), the Centers for Disease Control and Prevention (CDC) determined that blood lead concentrations above $10\text{ }\mu\text{g dl}^{-1}$ present a risk to human health. In the past, this value was as high as $60\text{ }\mu\text{g dl}^{-1}$, but CDC decreased it repeatedly [7]. Some scientists continue to push for CDC to lower it even further. Neither ATSDR nor EPA have determined levels of external exposure below which adverse health effects are not expected to occur in children.

Exposure Assessment

Numerous monitoring programs in the United States track blood lead levels in the population. CDC's National Health and Nutrition Examination Survey (NHANES) analyzes blood lead data in citizens across the United States. In 2001–2002, the geometric mean blood levels in the population was between 1.5 and 1.6 $\mu\text{g dl}^{-1}$. NIOSH's Adult Blood Lead Epidemiology and Surveillance Program collects data from participating states, which require that all laboratories report adult blood lead levels that exceed 25 $\mu\text{g dl}^{-1}$ to the state department of health. Finally, CDC's Childhood Blood Lead Surveillance System is similar to NIOSH's program, but reports only on children less than 72-months old.

To estimate current and future exposures, it is also necessary to measure the levels of lead in the environment. EPA uses two models that relate environmental lead levels to predicted blood lead levels: (a) the integrated exposure uptake biokinetic model for children, and (b) the adult lead methodology for adults. These models take into account lead's multiple exposure pathways (ingestion and inhalation) as well its multiple exposure media (air, dust, food, soil, and water). The models allow scientists to use measures of external exposure and knowledge about the toxicokinetics of lead to estimate total current external exposure as well as to predict lifetime dose [8].

Risk Characterization

The goal of this step is to determine the risk of having an exposure above the "safe" level in the population. Although many scientists believe this level should be lower, the US government generally considers 10 $\mu\text{g dl}^{-1}$ to be safe for all populations exposed nonoccupationally, including children. OSHA's standards, on the other hand, use a blood lead level of 40 $\mu\text{g dl}^{-1}$ across the working lifetime [9]. This is higher than CDC's level owing to the fact that OSHA must balance health with feasibility concerns.

According to CDC, in 2006, there were approximately 310 000 children with blood lead levels above 10 $\mu\text{g dl}^{-1}$ living in the US. With regard to adults, 35 states in 2002 reported over 10 500 adults with blood lead levels of 25 $\mu\text{g dl}^{-1}$ or greater. Almost 1900 of these possessed levels of 40 $\mu\text{g dl}^{-1}$ or greater.

It should be noted that many studies have now documented health effects at much lower levels than

these. Additionally, these values are not indicative of lifetime dose, nor do they necessarily reflect peak exposure levels during some of the critical windows of vulnerability, such as during development. Finally, these statistics may not reflect high exposures occurring in the small population of people who work with lead or who live near lead-contaminated sites.

Occupational Risk Management in the United States

OSHA's standard for lead in general industry was finalized in 1978 and allows workers to attain blood lead levels up to 40 $\mu\text{g dl}^{-1}$ over their working lifetimes. Many scientists now believe, based on an extensive body of new evidence, that OSHA's lead standards should protect workers both from the acute effects of recent dose and also from the chronic effects of cumulative dose, and that allowing blood lead levels up to 40 $\mu\text{g dl}^{-1}$ does not accomplish either goal. Given evidence for chronic health effects at doses lower than the current standard, the ability to measure cumulative dose, and the availability of technology to limit exposure, some scientists believe a reassessment of the lead standards is overdue [10, 11].

End Notes

^a. Antiknock agents are gasoline additives used to reduce engine knocking and increase the fuel's octane rating.

Lévy Processes in Asset Pricing

The main empirical motivation for using Lévy processes in finance comes from fitting asset return distributions. Consider the daily (either continuous or simple) returns of Standard & Poor's 500 index (SPX) from January 2, 1980 to December 31, 2005. We plot the histogram of normalized (mean zero and variance one) daily simple returns in Figure 1, along with the standard normal density function. The maximum and minimum (which all occurred in 1987) of the normalized daily returns are about 7.9967 and -21.1550 . Note that, for a standard normal random variable Z , $P(Z < -21.1550) \approx 1.4 \times 10^{-107}$; as a comparison the whole universe is believed to have existed for 15 billion years or 5×10^{17} seconds.

Clearly the histogram of SPX displays a high peak and two asymmetric heavy tails. This is not only true for SPX but also for almost all financial prices, e.g., worldwide stock indices, individual stocks, foreign exchange rates, interest rates. In fact it is so evident that a name “leptokurtic distribution” is given, which means the kurtosis of the distribution is large. More precisely, the kurtosis and skewness are defined as $K = E\left(\frac{(X-\mu)^4}{\sigma^4}\right)$, $S = E\left(\frac{(X-\mu)^3}{\sigma^3}\right)$. For the standard normal density $K = 3$, and if $K > 3$, the distribution is called *leptokurtic* and the distribution will have a higher peak and two heavier tails than that of the normal distribution. For the SPX data, the sample kurtosis is about 42.23. The skewness is about -1.73 ; the negative skewness indicates that the left tail is heavier than the right tail. The classical geometric Brownian motion model (see **Simulation in Risk Management; Volatility Smile; Weather Derivatives**), which models the stock price as $S(t) = S(0)e^{\mu t + \sigma W_t}$ with W_t being the standard Brownian motion (see **Large Insurance Losses Distributions; Risk-Neutral Pricing; Importance and Relevance; Default Correlation**), is inconsistent with this feature, because in this model the return, $\ln(S(t)/S(0))$, has a normal distribution. Lévy processes, among other processes, have been proposed to incorporate the leptokurtic feature.

Overview

A stochastic process X_t is a Lévy process if it has independent and stationary increments and a stochastically continuous sample path, i.e., for any $\varepsilon > 0$, $\lim_{h \downarrow 0} P(|X_{t+h} - X_t| > \varepsilon) = 0$. Therefore, Lévy processes provide a natural generalization of the sum of independent and identically distributed (i.i.d.) random variables. The simplest possible Lévy processes are the standard Brownian motion $W(t)$, Poisson processes $N(t)$, and compound Poisson processes $\sum_{i=1}^{N(t)} Y_i$, where Y_i are i.i.d. random variables.

Of course, one can combine the above processes to form other Lévy processes. For example, an important class of Lévy processes is the jump-diffusion process (see **Default Risk**) given by $\mu t + \sigma W(t) + \sum_{i=1}^{N(t)} Y_i$, where μ and σ are constants. Interestingly, as per the famous Lévy–Itô decomposition the converse is also true. More precisely, any Lévy process can be written as a drift term μt , a Brownian motion with variance and covariance matrix $\mathbf{A}$, and a possibly infinite sum of independent compound Poisson processes that are related to an intensity measure $\nu(\mathbf{dx})$. This implies that a Lévy process can be approximated by jump-diffusion processes. This has important numerical applications in finance, as jump-diffusion models are widely used in finance.

The triplet $(\mu, \mathbf{A}, \nu)$ is also linked to the Lévy–Khinchin representation, which states that the characteristic function of a Lévy process X_t can be written in terms of $(\mu, \mathbf{A}, \nu)$ as

$$\frac{1}{t} \log E[e^{iz'X_t}] = -\frac{1}{2} z' \mathbf{A} z + i \mu z + \int_{\mathbb{R}^d} (e^{iz'x} - 1 - iz'x I_{\{|x| \leq 1\}}) \nu(\mathbf{dx}) \quad (1)$$

The representation suggests that it is easier to study Lévy processes *via* Laplace transforms and then numerically invert Laplace transforms. For numerical algorithms of Laplace inversion, see Abate and Whitt [1], Craddock *et al.* [2], and Petrella [3]. Some of the infinite activity Lévy processes may not have an analytical form for the intensity measure ν , although the probability density of X_t can be obtained explicitly; see, e.g., the generalized hyperbolic model in Eberlein and Prause [4].

There are two types of Lévy processes, jump-diffusion and infinite activity Lévy processes. In jump-diffusion processes, jumps are considered rare events, and in any given finite interval there are only finite number of jumps. Examples of jump-diffusion models in finance include Merton's [5]

Figure 1 Comparison of the histogram of the normalized daily returns of S&P 500 index (from January 2, 1980 to December 31, 2005) and the density of $N(0,1)$. Note the feature of a high peak and two heavy tails (i.e., the leptokurtic feature)

model, in which the jump size Y has a normal distribution, and the double exponential jump-diffusion model in Kou [6], in which Y has a density $f_Y(y) = p \cdot \eta_1 e^{-\eta_1 y} 1_{\{y \geq 0\}} + q \cdot \eta_2 e^{\eta_2 y} 1_{\{y < 0\}}$. The double exponential jump-diffusion model leads to analytical solutions for path-dependent options, such as barrier and lookback options, and analytical approximations of finite-horizon American options, thanks to the memoryless property of exponential density (see [7–10]; **Equity-Linked Life Insurance; Credit Migration Matrices**). The economic justification of the double exponential jump-diffusion model, including the rational expectations equilibrium and the consideration from behavioral finance, is discussed in [6].

For infinite activity Lévy processes, in any finite time interval there are infinitely many jumps. Many of these models can be constructed *via* Brownian subordination, i.e., $W(\tau(t))$, where $\tau(t)$ is a subordinator, which is an increasing Lévy process. The subordinator must have no diffusion component (i.e., with only positive jumps and a positive drift); see Cont and Tankov [11, p. 88]. For example, if the subordinator $\tau(t)$ is a gamma process, then $W(\tau(t))$ leads to the variance gamma model (see Madan and Seneta [12] and Madan *et al.* [13]; **Extreme Values**

in Reliability). If the subordinator $\tau(t)$ is an inverse Gaussian process, then $W(\tau(t))$ leads to the normal inverse Gaussian model (see Barndorff-Nielsen [14] and Rydberg [15]).

There is a large literature on Lévy processes in finance, including several excellent books, e.g., the books by Cont and Tankov [11] and Kijima [16]. The book [11] also discusses the issue of hedging in incomplete markets (see **Equity-Linked Life Insurance; Individual Risk Models; Nonlife Insurance Markets; Risk Measures and Economic Capital for (Re)insurers**), as Lévy processes lead to incomplete markets, and the complete replication of an option payoff is impossible. One can also use rational expectations in Lucas [17] and Stokey and Lucas [18] to choose a risk-neutral measure to price derivative as in Kou [6]. Some additional topics related to Lévy processes are provided below:

1. In terms of computational issues, see Cont and Voltchkova [19] and d’Haullin *et al.* [20] on numerical methods *via* solving partial integrodifferential equations, and Feng and Linetsky [21] and Feng *et al.* [22] on how to price path-dependent options numerically *via* variational methods and extrapolation.

2. In terms of applications, see the references in [23] for applications of Lévy processes in fixed income derivatives (*see Credit Risk Models; From Basel II to Solvency II – Risk Management in the Insurance Sector; Credit Migration Matrices*) and term structure models, and the references in [24] for applications in credit risk and credit derivatives (*see Dynamic Financial Analysis*).
3. Statistical inference and econometric analysis for Lévy processes are discussed in the book by Singleton [25].

Some Difficulties

The Volatility Clustering Effect

In addition to the leptokurtic feature, returns distributions also have an interesting dependent structure, called the *volatility clustering effect* (*see* Engle [26]; **Default Correlation**). More precisely, the volatility of returns (which are related to the squared returns) are correlated, but asset returns themselves have almost no autocorrelation. In other words, a large movement in asset prices, either upside or downside, tends to generate large movements in the future asset prices, although the directions of the movements are unpredictable.

In particular, any model for stock returns with independent increments (such as Lévy processes) cannot incorporate the volatility clustering effect. However, one can combine Lévy processes with other processes (e.g. [27, 28]) or consider time-changed Brownian motion and Lévy processes to incorporate the volatility clustering effect. More precisely, if $\tau(t)$ contains a diffusion component (i.e., not a subordinator), then $W(\tau(t))$ and $X(\tau(t))$ may have dependent increments and no longer be Lévy processes (*see* Carr *et al.* [29, 30] and Carr and Wu [31]).

Difficulties in Distinguishing Tail Behavior

Although the main empirical motivation for using Lévy processes in finance comes from the fact that asset return distributions tend to have tails heavier than those of normal distribution, it is not clear how heavy the tail distributions are, as some people favor power-type distributions while others prefer exponential-type distributions, although, as pointed out in Kou [6, p. 1090], the power-type right tails cannot be used in models with continuous

compounding as they lead to infinite expectation for the asset price. We will stress that, quite surprisingly, it is very difficult to distinguish power-type tails from exponential-type tails from empirical data, unless one has extremely large sample size perhaps in the order of tens of thousands or even hundreds of thousands (*see* Heyde and Kou [32]). Therefore, it is very difficult to choose a good model based on the limited empirical data alone.

A good intuition may be obtained by simply looking at the quantiles for both standardized Laplace (with a symmetric density $f(x) = \frac{1}{2}e^{-x}I_{[x>0]} + \frac{1}{2}e^x I_{[x<0]}$) and standardized t distributions with mean 0 and variance 1. The right quantiles for the Laplace and normalized t densities with degrees of freedom from 3 to 7 are given in Table 1.

This table shows that Laplace distribution may have higher tail probabilities than those of t distributions, even if asymptotically the Laplace distribution should have lighter tails than those of t distributions. For example, regardless of the sample size, the Laplace distribution may appear to be heavier tailed than a t distribution with degrees of freedom (d.f.) 6 or 7, up to the 99.99 percentile. To distinguish the distributions, it is necessary to use quantiles with very low p-values and correspondingly large samples. If the true quantiles have to be estimated from data, then the problem is even worse, as the sample standard deviations need to be considered, resulting in sample sizes typically in the tens of thousands or even hundreds of thousands necessary to distinguish power-type tails from exponential-type tails.

Of course, one can use intraday data to have more sample sizes. However, intraday data may involve market microstructures, resulting in totally different empirical methods. For example, there is no single price due to the bid–ask spread, and the order size information is also relevant (*see* O’Hara [33]).

Table 1 Right quantiles for the Laplace and normalized t distributions with d.f. from 3 to 7

Probability (%)	Laplace	t_7	t_6	t_5	t_4	t_3
1	2.77	2.53	2.57	2.61	2.65	2.62
0.1	4.39	4.04	4.25	4.57	5.07	5.90
0.01	6.02	5.97	6.55	7.50	9.22	12.82
0.001	7.65	8.54	9.82	12.04	16.50	27.67

Risk due to Model Selection

The difficulties in distinguishing tail distributions indicate that there is a risk associated with choosing a proper model (see **Causal Diagrams**), as whether one prefers to use power-type distributions or exponential-type distributions is a subjective issue, which cannot be easily justified empirically. This also has implications in risk management, which is sensitive to the choice of models.

For example, a controversy in axiomatic approaches to risk measures is whether one should use value-at-risk or VaR (see **Simulation in Risk Management; Credit Scoring via Altman Z-Score; Extreme Value Theory in Finance**), which is a measure based on quantiles, or the tail conditional expectation.

The tail conditional expectation satisfies a set of axioms based on subadditivity (Artzner *et al.* [34]), while the VaR also satisfies a different set of axioms based on comonotonic (see **Comonotonicity**) subadditivity (Heyde *et al.* [35]), which is consistent with the prospect theory in behavioral finance. The intuition behind subadditivity is that merger should reduce risk, although the intuition may not be valid in the presence of the limited liability law. Furthermore, both VaR and the tail conditional expectation take into consideration the loss beyond the threshold, because VaR at a higher quantile (e.g., at 97.5%) can also be represented as tail conditional median (e.g., at 95%).

Whether one should measure risk by using VaR or the tail conditional expectation depends on whether the measure is used for internal or external risk management. The main advantage of VaR is that it is more robust against model assumptions and misspecifications, thus making it more suitable to generate more consistent results for external risk regulations and law enforcement. Indeed, VaR is widely used in governmental regulation, e.g., the recent Basel (II) (see **From Basel II to Solvency II – Risk Management in the Insurance Sector; Credit Risk Models; Informational Value of Corporate Issuer Credit Ratings**) banking regulations. On the other hand both the tail conditional expectation and VaR may be suitable for internal risk management.

Life Insurance Markets

What is Life Insurance?

There are two main types of life insurance policy: protection and investment policies. Protection policies are designed to provide a benefit (typically a lump-sum payment) following a specific event (such as death) if it occurs during the period (or term) for which the policy is valid, but nothing if the event does not occur during that time. Investment policies last until the policy is cancelled, and accumulate a cash value in the form of savings over the life of the policy. Pensions (*see* **Longevity Risk and Life Annuities; Risk Classification/Life; Securitization/Life**) are a form of life assurance that allow policyholders to build up a fund over the course of their working life, which is then converted into a payment on retirement. This payment may take the form of an annuity (*see* **Equity-Linked Life Insurance; Insurance Applications of Life Tables; Multistate Models for Life Insurance Mathematics**), which in its simplest form provides a stream of income until the insured person dies; thus insuring them against the risk that they will run out of resources because they live too long.

Life insurance policies can be bought either by the person whose life is insured, or by a third party. In cases where the third party is also the beneficiary, insurers try and limit the sale of life insurance policies to those who have an insurable interest (sometimes referred to as *cestui qui vit*), or in other words, to people who will materially suffer if the insured person dies. This is to reduce the possibility of moral hazard (*see* **Options and Guarantees in Life Insurance; Moral Hazard**), or that the beneficiary will actively seek the death of the insured.

Life insurance policies are also a popular form of employee benefit, in which case the third-party purchasing insurance and the beneficiary will differ. Within this group market, individuals will, typically, not be rated on their risk profile separately. Therefore, the value of the benefit to the individual will, in part, depend on how risky they are compared to the rest of the group.

Why Purchase Life Insurance?

Households typically have three motives for buying life insurance products: the desire to smooth

consumption over time, bequests, and tax advantages. The strength of the first two of these motives will depend on the individual or household, while the tax advantages associated with life insurance policies will depend on the fiscal regimes operating in individual countries.

The classic explanation of the consumption-smoothing motive for entering life insurance markets is provided by Yaari [1]. This uses a life-cycle model to show that for a consumer facing an uncertain lifetime, with no bequest motive, the optimal investment would be 100% annuitization. If the consumer does not wish to leave any bequests, then the best way to insure themselves against the risk of living too long is annuitization. More recently, [2] calculates that a 65-year-old male would be willing to give up one-third of his wealth to gain access to an actuarially fair annuities market.

At the level of the household, rather than the individual, annuities are not the only life insurance policy that can help with consumption smoothing. Life insurance policies such as term assurance (which pays out if the individual dies within a given period) can help working-age individuals protect their family against the loss of future labor earnings [3]. If life insurance products are not available, then one potential outcome could be inefficient overcaution, particularly on the part of those with a strong bequest motive, such as parents with young children.

There is some debate over the extent to which the bequest motive drives the purchase of life insurance. In the United States, 78% of couples aged over 70 own a protection-style life insurance policy on at least one member [4]. These holdings do not appear to be driven by the desire to protect the survivor against a drop in income. This leads to the hypothesis put forward by Bernheim [5] that life insurance is being held by elderly households to offset an excessive level of mandatory annuitization in the form of social security. This annuity-offset model would suggest the existence of a very strong bequest motive. However, tests of the annuity-offset model by Brown [4] could not find evidence that elderly households were buying term life insurance policies to leave a bequest. This finding has important implications for government policy – if mandatory annuitization leads to overannuitization because of a strong bequest motive, this would suggest that welfare could be improved by allowing households greater choice over the extent of annuitization. The strength of the

bequest motive is also questioned by Holtz-Eakin *et al.* [6], who find that purchase of life insurance by small business owners is insufficient to cover estate taxes. As this implies that the business may have to be sold, rather than stay within the family, following the owner's death, it indicates that the bequest motive is weaker than what the debate around estate taxes on small businesses would suggest.

Do Households Buy Enough Life Insurance?

There are different definitions of adequate life insurance ranging from a definition based on the utility of the survivor to simpler definitions that look at the ability of survivors to maintain their lifestyle. Whichever definition is used, however, the consensus is that there is significant underinsurance.

For example, [7] examines the adequacy of life insurance among married American households approaching retirement and finds that more than half the wives and one-quarter of the husbands in the sample are inadequately protected against the death of their spouse. In the case of wives, 15% would have suffered a reduction in living standards of greater than 40%. In other words, they suffered from severe underinsurance. A further 15% of wives would have suffered a reduction in income of between 20 and 40% if their husband had died in the year of the sample, and so also faced significant underinsurance. For husbands, 5 and 6% faced severe and significant underinsurance, respectively. One explanation put forward for this underinsurance is that people do not like thinking about death.

Similarly, the results of [8] suggest that there is significant underannuitization outside the social security system, even allowing for the existence of incomplete markets (*see Equity-Linked Life Insurance; Individual Risk Models; Weather Derivatives*).

The Role of Government

The extent to which people buy life insurance policies will depend partly on the role of government. Governments, for example, set the tax regime; and tax advantages play an important role in the demand for life insurance. In addition, some government policies act as a substitute for life insurance, which potentially leads to crowding out. The extent to which social

security policies provide a backup income for survivors will, in part, determine the importance of life insurance for the household as a whole.

Most public pension policies combine insurance with redistribution. The redistribution may be deliberate, for example, lower-paid workers may be entitled to higher replacement ratios (the proportion of income that the pension replaces). However, differences in life expectation mean that systems with mandatory annuitization at a uniform price will also result in redistribution in favor of those with higher life expectancy, typically those on higher incomes. Brown [9] investigates the impact of this type of program and shows that, provided administration costs are low, complete annuitization is welfare enhancing even for those with lower than average life expectancy. This is because, in the absence of annuities, even individuals with a high-mortality risk would need to set aside resources to cover the risk that they will live longer than expected. In addition, the associated redistribution is much lower if it is measured on a utility-adjusted basis, rather than simply in financial terms.

The other key role of government is in setting the regulatory environment in which insurance companies operate. This will have far-reaching implications for their business models, including the extent to which they can use risk pricing; the way in which they interact with customers, particularly on consumer protection issues such as suitability and treating customers fairly; and the amount of regulatory capital (*see Credit Migration Matrices; Operational Risk Modeling*) that they need to hold.

Commitment Issues

One of the features of life insurance products, particularly investment policies, is that they often involve long-term contracts. Unfortunately, events may make it difficult for consumers to commit over the long run. For example, [10] shows that in the United Kingdom only 60% of regular premium policies are still in force after 4 years. This lack of persistency is attributable to many factors. The Financial Services Authority [11] shows that 58% of lapses are because of income and affordability issues, with a further 10% attributed to marital or domestic reasons. The extent to which these types of events are predictable will have an impact on the desirability of an individual taking out a long-run investment policy.

However, there may be other reasons for a lack of commitment. When thinking about the purchase of life insurance products over time, there are two types of risk that consumers consider – the short-term event risk that an accident occurs within a period, and the long-term classification risk, or that changes in the consumer's type will lead to variability in future premiums. Consumers who receive positive (better than average) news about their risk characteristics will have an incentive to switch providers to take advantage of their improved health. This will make it difficult for them to commit to a long-term contract, and for insurance companies, in turn, to provide full insurance against classification risk. Hendel and Lizzeri [12] show that markets have got round the problem of lack of commitment from consumers by front-loading premium payments within long-term policies. This acts as a partial lock-in for consumers. The results show that contracts that are more front loaded have higher persistency (lower lapses), and hence keep a higher proportion of customers in the long run. As better risk types are more likely to switch provider, contracts with higher lapse rates retain worse risk pools. While front loading comes at a cost because it makes it harder for households to smooth consumption, [12] estimates that this cost is low. The benefits of front loading are that consumers suffer very little reclassification risk, so that insurance companies in the United States are able to commit to guaranteed renewable contracts for life insurance without the need for regulation.

Risk Pricing

Risk pricing (*see Actuary; Risk Measures and Economic Capital for (Re)insurers*) is the method that insurers use to try to price the risks associated with a specific group of individuals to reflect the likelihood that they will claim. If insurers are unable to use risk-pricing, for example because of government legislation designed to reduce age or sex discrimination, the result is likely to be that: either the higher risk groups will find it difficult to obtain life insurance; or that those with a better risk profile will tend not to buy insurance, because the price that they face is too high. One of the benefits of risk pricing has been the development of “impaired life” insurance for those with significant health problems such as diabetes – a group who would previously have struggled to get cover.

At the decumulation (in payment) stage, the risk for the insurer from pensions is longevity risk – in other words, the possibility that the insurer may have underestimated the length of time the pensioner will survive. For other forms of life insurance, the typical risk is mortality risk, the risk that the policyholder will die. One of the problems with correctly pricing annuities is predicting changes to longevity risk, as life expectancy has been rising sharply over recent decades. The extent to which the rate of change of improvements in life expectancy can be expected to continue will have a big impact on the profitability of annuity contracts, as well as on bulk-buyout transactions (whereby life insurers take over either another insurer's book of business or the pension risks associated with individual companies' defined benefit pension schemes). Blake *et al.* [13] provides a discussion on how these risks have changed over time by examining longevity fan charts. Given significant differences in life expectancy for men and women, it will be particularly important to account for gender differences in risk-pricing calculations for life insurance products such as annuities.

One of the problems for an insurer of accurately pricing the risks associated with a particular product offering is the existence of asymmetric information. Customers will typically know more about their own personal risk characteristics than their insurers, and this can lead to adverse selection – the people taking out insurance are, in fact, more risky for the insurance company than their observable characteristics would suggest. In general, with insurance, it can be difficult to disentangle the impact of adverse selection and moral hazard (whereby the existence of insurance changes people's behavior). In other words, if claims are higher for those with insurance than would be the case for a seemingly identical population without insurance, it is impossible to tell if this is the result of moral hazard or adverse selection. For most life insurance products, however, the problems of moral hazard are typically thought to be less than would be the case for some other types of insurance. They can also be more easily managed, for example, through the use of clauses that exclude payouts in the event of a suicide within a certain time period. However, adverse selection definitely exists, although it may not show up in the simple headline number of amount insured.

For example, Finkelstein and Poterba [14] demonstrates that in the UK annuities market, mortality patterns are consistent with the existence of asymmetric

information and that high-risk individuals self-select features of insurance contracts that are more valuable to them, for a given price, than would be true for low-risk individuals. The contract features where this self-selection occurs are the time profile of annuity payments, and whether the annuity will make payments to the annuitant's estate in the event of death. Annuitants who live longer tend to have selected back-loaded payment streams (where income rises over time), while those who die early will often have selected an annuity type that makes payments to their estate in the event of death. These selection effects are large – the mortality differences between those who opt for back-loaded *versus* non-back-loaded annuities are larger than the mortality differences between male and female annuitants. Self-selection does not appear to be prevalent in the amount of the initial annuity payment, which is equivalent to a measure of the amount insured. This may explain the mixed nature of the results in previous studies on adverse selection in insurance markets, which tended to concentrate on the amount of payment in the event that the insured risk occurs.

Buying Life Insurance

One of the key issues in the sale of life insurance products is the role of advice. Life insurance products can be complex and difficult to compare, meaning that consumers face high search costs. This suggests a natural role for tailored, face-to-face advice. The important role of full advice, in the regulatory sense, is reinforced by regulation such as the “suitability” requirement in the United Kingdom, whereby sellers need to demonstrate that financial products are suitable for purchasers.

However, other routes to market can have a big impact on the search costs that consumers face, particularly on simpler products such as term assurance. The most obvious source of reduced search costs is the rise of online insurance comparison sites. Brown and Goolsbee [15] looks at the impact of online insurance sites on the prices paid for term assurance by different groups. They show that the faster a group adopted the Internet, the faster the prices of term assurance dropped for that group and that these changes cannot be explained by changes in mortality. They show that the rise of the Internet in the United States reduced the price of term life assurance by between 8 and 15%, equivalent to an annual increase

in the consumer surplus of \$115 and \$215 million on these policies.

Lifetime Models and Risk Assessment

Researchers in different fields have investigated risk assessment using methods for lifetime data. Lifetime data have been referred to as *survival time data* in biomedical research, as *reliability data* in engineering applications, and as *time-to-event data* in social sciences. In general, lifetime data can be defined as the times to the occurrence of a certain event. Statistical methods for analyzing lifetime data include the definition of survival time, censored data, prediction of probability of survival, prediction of instantaneous hazards, evaluation of cure rates, etc. We review different types of lifetime data, methods for estimating hazard and survival functions, and methods for risk assessment. Detailed information can be found in the following books: Kalbfleisch and Prentice [1], Nelson [2], Cox and Oakes [3], Fleming and Harrington [4], Andersen *et al.* [5], Marubini and Valsecchi [6], Klein and Moeschberger [7], Lawless [8], Lee and Wang [9], and others. Hougaard [10] gives good descriptions of analytical methods for multivariate survival data. Bayesian survival analysis can be found in Ibrahim *et al.* [11]. A Bayesian approach for reliability models and risk assessment is given by Singpurwalla [12]. Lifetime models, based on stochastic processes hitting a boundary, have been investigated by Whitmore [13, 14], Lu [15], Whitmore *et al.* [16], Onar and Padgett [17], Aalen and Gjessing [18], Padgett and Tomlinson [19, 20], and others. A review of threshold regression for risk assessment, based on the concept of a first hitting time (FHT), can be found in Lee and Whitmore [21].

Important Parametric Distributions for Lifetime Models

Several parametric distributions have been used in analyzing lifetime data, including the exponential, Weibull, inverse Gaussian, gamma and generalized gamma, lognormal, log-logistic, and various accelerated failure-time distributions.

Censored and Truncated Data

In practical situations, it often happens that we cannot observe all the subjects in the study for a complete lifetime data. For example, patients may be either lost to follow-up or still alive at the end of the study. These kinds of data are called *censored data*. There are several types of censoring mechanisms.

1. Type I censoring

Each individual has a fixed potential censoring time $C_i > 0$ such that lifetime T_i is observed if $T_i \leq C_i$; otherwise, we only know that $T_i > C_i$.

2. Type II censoring

In a random sample of size n , we only observe the r smallest lifetimes $t_{(1)} \leq t_{(2)} \leq \dots \leq t_{(r)}$, where $r < n$. Both type I and type II censored data, as defined above, are also referred to as *being right censored*.

3. Independent random censoring

It is common that the censoring mechanism is random and independent of the failure process. In this situation, the lifetimes T_i and censoring times C_i are independent, for $i = 1, \dots, n$. Letting I denote an indicator function and defining $\delta_i = I(T_i \leq C_i)$, the data observed from n individuals in a random censoring scheme are therefore pairs (t_i, δ_i) , for $i = 1, \dots, n$, where $t_i = \min(T_i, C_i)$.

4. Interval censoring

In longitudinal studies or clinical trials, interval censoring may occur when a patient has periodic follow-ups and the patient's event time is only known to fall in an interval $(L_i, R_i]$, for $i = 1, \dots, n$.

5. Current status data

Interval censored data where the intervals are either (C_i, ∞) or $(0, C_i]$ are called *current status data*. These data arise when subject i is examined once at time C_i and the event occurrence is determined at the same time C_i . For example, the time to tumor occurrence of a mouse can only be checked at the time of autopsy.

6. Truncation

Truncation is a condition where only those individuals who experience certain events can be observed by the investigator. For example, left truncation occurs when individuals of different ages enter a retirement study (i.e., delayed entry) and are followed until either an event or right censoring occurs. Individuals

who die before retirement cannot be included in the study. In AIDS studies, right truncation often occurs in that individuals who are yet to develop AIDS are neither observed nor are they included in the study sample.

Calendar or Running Time

In many applications, the natural time scale of the failure process is not calendar or clock time but rather some measure of use or cumulative exposure. Cox and Oakes [3, Section 1.2, pp. 3–4] point out that “often the *scale* for measuring time is clock time, although other possibilities certainly arise, such as the use of operating time of a system, mileage of a car, or some measure of cumulative load encountered” Lawless [8, p. 6] also states that “Miles driven might be used as a time scale for motor vehicles, and number of pages of output for a computer printer or photocopier.” This kind of alternative time scale is sometimes referred to as an *operational time* or *running time*. Survival analysis can be done in terms of either calendar time or operational time.

Estimation of Survival and Hazard Functions

The following are the basic theoretical quantities in lifetime models and related risk assessment:

1. Failure-time probability density function $f(t)$

This function describes the rate at which items will fail at any given time $T = t$.

$$f(t) dt = Pr(T \in [t, t + dt)) \quad (1)$$

2. Survival function $S(t)$

This function is the probability that an item will fail after time t .

$$S(t) = Pr(T > t) \quad (2)$$

3. Hazard function $h(t)$

This function describes the rate of failure at time t among items that have survived to time t .

$$h(t) = -\frac{d \ln S(t)}{dt} = \frac{f(t)}{S(t)} \quad (3)$$

4. Cumulative hazard function $H(t)$:

This function is the aggregate hazard to which an item is exposed up to time t .

$$H(t) = \int_0^t h(u) du = -\ln[S(t)] \quad (4)$$

Estimating the hazard function and survival function is the major focus of lifetime data analysis. From a process point of view, Aalen and Gjessing [22] present a good understanding of the hazard function.

If the data have already been grouped into intervals, a life table can be constructed to assess survival probabilities and hazard rates at different intervals. For parametric models, likelihood-ratio testing procedures and parametric regression models for handling censored and/or truncated data have been well developed.

Kaplan – Meyer Nonparametric Estimator for Survival Function

When individual lifetimes can be observed, the product-limit nonparametric estimator of the survival function developed by Kaplan and Meyer [23] is the most widely used method for estimating survival functions. In the situation where n distinct lifetimes are observed without censoring such that their ordered values are $t_{(1)} < t_{(2)} < \dots < t_{(n)}$, the survival function can be estimated by

$$\hat{S}(t) = \prod_{t_{(i)} \leq t} \frac{(n - i)}{(n - i + 1)} \quad (5)$$

In general, suppose d_i subjects have lifetime $t_{(i)}$, $1 \leq i \leq n$. Let Y_i denote the stochastic process indicating the number of individuals at risk at time $t_{(i)}$. Then

$$\hat{S}(t) = \prod_{t_{(i)} \leq t} \left(1 - \frac{d_i}{Y_i}\right) \quad (6)$$

Nelson – Aalen Estimator for Cumulative Hazard Function

In a reliability context, Nelson [24] introduced the following estimator for the cumulative hazard function

$$\hat{H}(t) = \sum_{t_{(i)} \leq t} \left(1 - \frac{d_i}{Y_i}\right) \quad (7)$$

Using methods of counting processes, Aalen [25] also derived this estimator, which is now referred to as the *Nelson – Aalen estimator*.

Semiparametric Proportional Hazards Models and Cox Regression

Cox [26] introduced the proportional hazards (PH) model. Given a covariate vector $\mathbf{X} = \mathbf{x} = (\mathbf{x}_1, \dots, \mathbf{x}_n)$, this model assumes that the hazard function for lifetime T is of the form

$$h(t|\mathbf{X} = \mathbf{x}) = h_0(t) \exp(\boldsymbol{\beta}'\mathbf{x}) \quad (8)$$

where $\boldsymbol{\beta}$ is a vector of regression coefficients and $h_0(t)$ denotes the baseline hazard function.

For any two individuals with covariate vectors $\mathbf{X}_1 = \mathbf{x}_1$ and $\mathbf{X}_2 = \mathbf{x}_2$, the ratio of their hazard rates is constant through time.

$$\frac{h(t|\mathbf{X}_2 = \mathbf{x}_2)}{h(t|\mathbf{X}_1 = \mathbf{x}_1)} = \frac{h_0(t) \exp(\boldsymbol{\beta}'\mathbf{x}_2)}{h_0(t) \exp(\boldsymbol{\beta}'\mathbf{x}_1)} = \exp[\boldsymbol{\beta}'(\mathbf{x}_2 - \mathbf{x}_1)] \quad (9)$$

This quantity is called the *hazard ratio* (or *relative risk*) and is very useful in applications. For PH models, it can be shown that

$$S(t|\mathbf{X} = \mathbf{x}) = [S_0(t)]^{\exp(\boldsymbol{\beta}'\mathbf{x})} \quad (10)$$

where $S_0(t)$ is the baseline survival function.

Additive Hazards Models

In a PH model, as mentioned above, the covariates act multiplicatively on some unknown baseline hazard function. In an additive hazards regression model, the hazard rate at time t is assumed to be a linear combination of the covariate vector $\mathbf{X}$.

$$h(t|\mathbf{X} = \mathbf{x}) = \beta_0(t) + \boldsymbol{\beta}'\mathbf{x} \quad (11)$$

Therefore, in this model, the covariates act in an additive manner on an unknown baseline hazard function $\beta_0(t)$.

Accelerated Failure-Time Model

Given any lifetime t , the accelerated failure-time model is defined by the equation

$$S(t|\mathbf{X} = \mathbf{x}) = S_0[t \exp(\boldsymbol{\theta}'\mathbf{x})] \quad (12)$$

The factor $\exp(\boldsymbol{\theta}'\mathbf{x})$ is called an *acceleration factor* and indicates how a change in a covariate value changes the baseline time scale. Specifically, the hazard rate for an individual with covariate vector $\mathbf{X} = \mathbf{x}$ can be written as

$$h(t|\mathbf{x}) = \exp(\boldsymbol{\theta}'\mathbf{x}) h_0[t \exp(\boldsymbol{\theta}'\mathbf{x})] \quad (13)$$

Frailty Models

In multivariate survival analysis, the frailty model has become popular. In practice, a frailty is an unobservable random effect shared by subjects within a subgroup. In one formulation of frailty, a common random effect acts multiplicatively on the hazard rates of all members in the subgroup. The shared frailty model extends the PH regression model as follows. The hazard rate for the j th individual in the i th group is of the form

$$h_{ij}(t|\mathbf{x}_{ij}) = h_0(t) \exp[\sigma w_i + \boldsymbol{\beta}'\mathbf{x}_{ij}] \quad (14)$$

where w_i is the frailty shared by the i th group.

First Hitting Time Models and Threshold Regression

FHTs arise naturally in many types of stochastic processes. In a lifetime context, the state of the underlying process represents the strength of an item or the health of an individual. The item fails or the individual experiences a clinical endpoint when the process reaches an adverse threshold state for the first time. In many applications, the process is latent (i.e., unobservable). *Threshold regression* refers to FHT models with regression structures that accommodate covariate data. The parameters of the process, threshold state, and time scale may depend on the covariates.

An FHT model has two basic components: (a) a *parent stochastic process* $\{X(t)\}$ and (b) a *threshold*. The FHT is the time when the stochastic process first crosses the *threshold*. Whether the sample path of the parent process is observable or latent (unobservable) is an important distinguishing characteristic of the FHT model. Latent processes are the most common by far. As an example, we consider a Wiener process $\{X(t), t \geq 0\}$ with mean parameter μ , and variance parameter σ^2 as the parent stochastic process, and initial value $X(0) = x_0 > 0$.

In threshold regression, parameters μ , σ^2 , and initial value x_0 will be connected to linear combinations of covariates using suitable regression link functions, as illustrated below for some parameter, say θ .

$$g_\theta(\theta_i) = \mathbf{z}_i \boldsymbol{\beta} \quad (15)$$

Here g_θ is the link function, parameter θ_i is the value of parameter θ for individual i , $\mathbf{z}_i = (1, z_{i1}, \dots, z_{ik})$ is the covariate vector of individual i (with a leading unit to include an intercept term), and $\boldsymbol{\beta}$ is the associated vector of regression coefficients.

An identity function of form

$$\mu = \mathbf{z} \boldsymbol{\beta} = \beta_0 + \beta_1 z_1 + \dots + \beta_k z_k \quad (16)$$

might be used to link parameter μ to the covariates and a logarithmic function

$$\ln(x_0) = \mathbf{z} \boldsymbol{\gamma} = \gamma_0 + \gamma_1 z_1 + \dots + \gamma_k z_k \quad (17)$$

for the initial value parameter x_0 . Parameter σ^2 can be given an arbitrary value (say 1) because the process $\{X(t)\}$ is latent.

A running-time scale transformation can be accommodated by the threshold regression model. If $r(t)$ denotes the transformation of calendar time t to running time r , with $r(0) = 0$, and $\{X(r)\}$ is the parent process defined in terms of running time r , then the resulting process expressed in terms of calendar time is the process $X^*(t) = X[r(t)]$. A *composite running time* might be defined by

$$r(t) = \sum_{j=1}^J \alpha_j r_j(t) \quad (18)$$

where the $r_j(t)$ are different accumulation measures that can advance degradation or disease progression and the α_j are positive parameters that weight the contributions of the different measures.

As an example, consider a Wiener process with $x_0 > 0$ and the boundary as the zero level. It is well known that the FHT has an inverse Gaussian distribution if $\mu < 0$. The corresponding survival function $S(r|\mu, \sigma^2, x_0)$ can be written as

$$\Phi \left[\frac{\mu r + x_0}{\sqrt{\sigma^2 r}} \right] - \exp(-2x_0 \mu / \sigma^2) \Phi \left[\frac{\mu r - x_0}{\sqrt{\sigma^2 r}} \right] \quad (19)$$

where $\Phi(\cdot)$ is the cumulative distribution function (CDF) of the standard normal distribution. Lee

et al. [27] demonstrated how to use this model in analyzing AIDS data. Lee *et al.* [28] used the threshold regression model in assessing lung cancer risk to a large cohort of US railroad workers from diesel exhaust exposure. Bayesian methods for FHT models have been discussed by Pettit and Young [29] and Shubina [30, 31].

MEI-LING TING LEE

Linkage Analysis

In biology, a *trait* or character is a feature of an organism. Most biological traits including human health and physical characteristics are determined primarily by the chemical composition of the proteins created in cells. The composition and formation of these proteins are in turn determined by the genetic material. Genetic material is aligned in pairs of long strands called *chromosomes*. Roughly, for any given protein, there is a particular responsible location (called *locus*) on one of the chromosomes. The chemical sequence of the genetic locus on the chromosome determines the composition of a particular protein which, in turn, determines traits and their *phenotypes* [1]. The term *phenotype* refers to the state of the trait (e.g., the trait eye color has the phenotypes blue, brown, and hazel).

Discovering the genetic loci that correspond to particular traits of interest is an important scientific endeavor that can have profound impact on improving public health and/or creating major economic benefits. Many human diseases including various types of cancer, heart disease, and diabetes are known to have some underlying genetic predisposition [1, 2]. In medical studies, the determination of disease susceptibility loci is an important initial step in identifying genetic etiology and for effective intervention of these diseases. The identification of genetic loci that affect certain traits also has applications in plant and animal studies, such as for improving grain yield in rice and increasing milk production in cows.

Identification of the genetic loci that correspond to particular traits cannot be done by simply measuring the traits of interest in a sample of subjects and then comparing the traits with the subjects' chromosomal chemical sequences. Even with modern biotechnology and computing power, it is still impractical to determine the whole sequence, which is too long to be done under usual time and cost constraints. An often useful idea is to first localize the genetic loci that correspond to particular traits to a relatively small chromosomal region, which can be done using available fragments of the sequence from a subset of loci in the chromosomes. Such genetic loci are termed *marker loci*. There are numerous marker loci with known chromosomal positions spreading densely throughout the entire human genome. Thus,

the genetic loci that correspond to particular traits are likely to be close to some of these marker loci. Moreover, genetic materials at close-by loci tend to be inherited together, and thus a genetic marker close to a trait locus tends to be inherited together, which means the marker tends to be coinherited with the trait. *linkage analysis* aims to test for coinheritance of marker loci with particular traits.

Many useful methods for linkage analysis have been developed during the last few decades. The classical linkage analysis method uses the logarithm of odds (LOD) score, which is equivalent to the likelihood-ratio test statistic [3]. This method requires the specification of a detailed inheritance model for the trait. When such models can be correctly specified as in the case of a simple Mendelian disease, the LOD score method is the method of choice owing to the power optimality of the likelihood-ratio test (LRT). For complex traits, however, it is often impossible to correctly specify a detailed inheritance model for the trait. The so-called model-free method for linkage analysis may be used, which does not require to specify, *a priori*, an inheritance model for the trait of interest. Frequently, model-based methods are called *parametric methods*, whereas model-free methods are called *nonparametric methods*. However, there is no sharp boundary that can clearly distinguish model-based analysis from model-free analysis, as both the theory and applications have considerable overlap [4, 5]. Traditionally, linkage methods for mapping qualitative traits are developed separately from those methods for mapping quantitative traits; many methods that are useful for both qualitative and quantitative traits are currently available. Most methods have been developed first for establishing linkage between two genetic loci (two point) and then extended to multipoint linkage analysis. The latter can be better suited for mapping complex traits; however, this often involves heavy computational burden. The rest of the article is devoted to a brief overview of the commonly used methods for linkage analysis.

Biological Basis of Linkage

A large number of loci spread densely throughout the whole genome (called *marker loci*) have been identified and their exact positions are known in the

chromosomes. The genetic material at these marker loci are segments of the DNA (deoxyribonucleic acid) whose inheritance from parents to offspring can be followed. The DNA segments at these marker loci are considerably variable between individuals. However, with modern biotechnology, it is straightforward to determine the polymorphic DNA sequences at these marker loci. Typically, at any marker locus, there exist only a few possible sequence values that the marker DNA sequences can take on. These values are termed *alleles*, and the pair of alleles obtained from an individual's marker loci in the pair of chromosomes comprise the *genotype*. An individual's genotype at a locus is called *homozygous* if the pair of alleles are identical and *heterozygous* if they differ. The arrangement of the alleles on the pairs of chromosomes is called the *phase*. The genotype data for multiple loci with the relevant phase information are the *haplotype*. Consider the simple case of a locus defined with two alleles, A_1 and A_2 . Denote the allele frequency of A_i in the population as $p_i, i = 1, 2$. If the genotype frequencies of A_1A_1 , A_1A_2 , and A_2A_2 in the population are p_1^2 , $2p_1p_2$, and p_2^2 , respectively, the so-called Hardy-Weinberg equilibrium (HWE) holds. If these frequencies are violated, it is said that there is a disequilibrium. Similarly, if frequencies of two alleles at two or more genetic loci (haplotype) do not satisfy the HWE, it is called *linkage disequilibrium* (LD) or *allelic association* [1].

The transmission pattern of genetic material from parents to offspring is of fundamental importance to linkage analysis. For each individual, one member of each pair of chromosomes is inherited maternally, and the other is inherited paternally. An offspring does not inherit a complete copy of the sequence that forms either of the parental chromosomes. Instead, each inherited chromosome represents a mixture of subsequences of the corresponding parental pair. The number of subsequences and the locations of their boundaries are random and independent for different offspring. The events that generate the boundaries are termed *crossovers*. An odd number of crossovers between two loci is termed a *recombination* [1].

Importantly, DNA segments at close-by loci on a single chromosome are often transmitted intact from parents to offspring without recombination between them. The recombination fraction, θ , between two loci is the relative frequency of recombination. If the two loci on a single chromosome are very close to

each other, the recombination fraction θ is close to 0, and if the two loci are far away then θ is close to 1/2. If two loci are on different chromosomes, $\theta = 1/2$. Two loci are often said to have linkage or said to be linked if they are close enough on the same chromosome that their segments cosegregate, i.e., $\theta < 1/2$ [1, 4]. The statistical test of no linkage between two loci is to test

$$H_0 : \theta = \frac{1}{2} \quad \text{against} \quad H_1 : \theta < \frac{1}{2} \quad (1)$$

The classical linkage test is based on the likelihood ratio, the logarithm of which is called a *LOD score* [1, 3], which is discussed next.

LOD Score Analysis

Frequently, a parametric model is employed to evaluate the probability of the observed pedigree data under certain assumptions on the recombination fraction θ and other parameters such as gene frequencies. The likelihood function for the i th pedigree will be denoted as $L_i(\theta)$. It is natural to use the LRT for linkage analysis. The likelihood-ratio function for the i th pedigree can be written as $\Lambda_i(\theta) = L_i(\theta)/L_i(0.5)$ and the LRT statistic is $LR = 2 \max_{0 \leq \theta \leq 0.5} \sum_i \log \Lambda_i(\theta)$. The LOD score function for the i th pedigree is $Z_i(\theta) = \log_{10} \Lambda_i(\theta)$, and for all independent pedigrees it is

$$Z(\theta) = \sum_i \log_{10} \Lambda_i(\theta) \quad (2)$$

and the maximum LOD score is simply $\max_{0 \leq \theta \leq 0.5} Z(\theta)$. Traditionally, the LOD score test is called *significant* if $\max_{0 \leq \theta < 0.5} Z(\theta) > 3$ [1, 3]. Next we discuss a few special cases of linkage analysis using the LOD score.

Phase-Known Pedigrees

In some animal cross studies, scientists can breed animals to the point where it is possible to determine which of their offspring are recombinants and which are nonrecombinants from the genotype data [1]. For the i th pedigree, suppose that the number of recombinants is r_i out of N_i meioses. We can estimate the recombination fraction θ using the likelihood $L(\theta) = \prod_i L_i(\theta)$, where

$$L_i(\theta) = \theta^{r_i} (1 - \theta)^{N_i - r_i}, \quad \theta \in [0, 0.5] \quad (3)$$

The maximum-likelihood estimate (MLE) of the recombination fraction θ , denoted as $\hat{\theta}$, is $\hat{\theta} = \min(\sum r_i / \sum N_i, 0.5)$, where the summation is over independent pedigrees.

Notice that $\theta = 1/2$ is on the boundary of the parameter space $[0, 1/2]$, and the classical LRT statistic $LR = \max_{0 \leq \theta \leq 0.5} 2 \log[L(\theta)/L(0.5)]$ for equation (3) has an asymptotic distribution with 50% point mass at 0 and 50% as $\chi^2(1)$, which is often denoted as

$$0.5\chi^2(0) + 0.5\chi^2(1) \quad (4)$$

If we assume the above distribution for the ordinary LRT statistic, the maximum LOD score, $\max_{\theta} Z(\theta) = LR/(2 \log 10)$, exceeds 3, and corresponds to a P value of 0.0001. In many genetic linkage analysis, a large number of loci are often being tested, and thus the P values are often required to be small to declare statistical significance due to concerns of multiple testing or multiple comparisons [6, 7].

Phase-Unknown Pedigrees

Consider a nuclear family with a pair of biallelic loci. Denote the alleles at the first locus by A_1/A_2 and the alleles at the second locus by B_1/B_2 . Consider the case that the father of the nuclear family is heterozygous at both loci, whereas the mother is homozygous at both loci. In this situation, there are two possible phases for the father: either he could have phase A_1B_1/A_2B_2 or he could have phase A_1B_2/A_2B_1 . Suppose the father's phase is A_1B_1/A_2B_2 , it is possible to determine whether each offspring is recombinant or nonrecombinant based on the genotype data, say we observe r_i recombinants out of N_i offspring ($N_i - r_i$ nonrecombinants). However, if the father's phase is actually A_1B_2/A_2B_1 , then with the same offspring data, these N_i offspring would have $N_i - r_i$ recombinants and r_i nonrecombinants. Because the two phases are equally likely in the absence of LD, the likelihood of the i th pedigree is given by

$$L_i(\theta) = 0.5\theta^{r_i}(1-\theta)^{N_i-r_i} + 0.5(1-\theta)^{r_i}\theta^{N_i-r_i}, \quad \theta \in \left[0, \frac{1}{2}\right] \quad (5)$$

The LOD score in equation (2) and the maximum LOD score can then be computed. The LRT statistic can be compared to the mixture distribution in equation (4) to obtain P values.

Locus Heterogeneity

It is possible that, in a proportion (say λ) of the pedigrees the two genetic loci are linked with a $\theta < 0.5$, and in others the two loci are not linked, which corresponds to $\theta = 0.5$. However, it is not known which pedigrees have linkage and which do not. Then the likelihood for a given pedigree may be written as

$$L_i(\lambda, \theta) = \lambda L_i(\theta) + (1 - \lambda) L_i\left(\frac{1}{2}\right), \quad \theta \in [0, 0.5] \quad (6)$$

where $L_i(\theta)$ can be either the phase-known or the phase-unknown likelihood in equation (3) or (5), or can be other more complicated pedigree likelihood functions. The corresponding LOD score is sometimes called *admixture LOD score* or *heterogeneity LOD score* [1, 8, 9]. Complex diseases often exhibit locus heterogeneity so that alleles at more than one locus confer susceptibility to the disease. Different pedigrees can have different alleles responsible for the same disease [1, 2]. The admixture likelihood in equation (6) is obviously the simplest case. One can detect linkage in the presence of locus heterogeneity using the LRT based on the admixture likelihood:

$$LR = 2\sum_i [\log L_i(\hat{\lambda}, \hat{\theta}) - \log L_i(1, 0.5)] \quad (7)$$

where $\hat{\lambda}$ and $\hat{\theta}$ are the MLEs of the mixture proportion λ and the recombination fraction θ . The asymptotic null distribution of the LRT in this case is nonstandard because under the null hypothesis λ is unidentifiable [9, 10].

Complicated Cases

In the above, we have been dealing with simple situations where the likelihood can be written down by inspecting the haplotypes passed from parents to offspring. However, various complications generally make such a simple approach impossible. For example, some key individuals may be unavailable for study and the trait locus is unknown and has to be estimated. Parametric LOD score can still be written down by assuming some *penetrance* models and other parameters. Penetrance models are used to quantify the probability of the observed phenotype conditional on each of the possible genotypes at the trait locus. For example, consider a disease locus with two alleles, Q and q . For a fully penetrant recessive disease,

we have

$$\Pr(\text{disease}|QQ) = 1 \quad (8)$$

and

$$\Pr(\text{disease}|qq) = \Pr(\text{disease}|Qq) = 0 \quad (9)$$

The LOD score method has been widely used for linkage analysis where the mode of inheritance of the loci must be specified. Under some conditions, however, several modes of inheritance appear plausible, and/or the penetrance may not be 0 or 1. Hence, non-parametric methods that require no assumptions about the mode of inheritance might be more appropriate for such situations which is common for mapping complex traits [2].

Identity-by-Descent Analysis

If a trait locus and a marker locus are linked, then pairs of relatives who have similar trait values should share more alleles *identity by descent* (IBD) (i.e., direct copies of the same parental allele), and relative pairs with different trait values should share fewer allele IBD, than expected by chance alone. Early studies often evaluated marker IBD relationships of sibling pairs, and this was later extended to pairs of other types of relatives. Thus these methods are often referred to as *sib-pair*, or *relative-pair* methods. Next we review methods for the evaluation of IBD-sharing probabilities.

Data of full siblings (same father and same mother) are often studied. If the siblings' parents are also typed for a marker, or if a large number of siblings are typed to permit the parental marker genotypes to be deduced, it is often possible to count the number of marker alleles that a sib pair shares IBD. There are also situations where for some sib pairs it is impossible to actually count the number of marker alleles shared IBD. Haseman and Elston [11] proposed to estimate the IBD allele sharing probabilities at a marker locus by utilizing the marker information available on the siblings and their parents. Let f_i be the prior probability that a pair of siblings shares, by virtue of their relationship alone, i alleles IBD. Thus for full siblings, $f_0 = 1/4$, $f_1 = 1/2$, $f_2 = 1/4$. Then by Bayes' theorem, the posterior probability that the siblings share i alleles IBD, given

the available marker data information I_m , is simply

$$\hat{f}_i = \frac{[f_i P(I_m | \text{the siblings share } i \text{ alleles IBD})]}{P(I_m)} \quad (10)$$

where $P(I_m) = \sum_{k=0}^2 f_k P(I_m | \text{the siblings share } k \text{ alleles IBD})$.

Haseman and Elston [11] considered only the availability of marker information on a pair of full sibs and up to two parents, but the same general expression can be used when other relatives are present, and pairs of relatives other than siblings can be easily accommodated [12]. In general, these estimates $\hat{f}_i$ depend on accurate estimates of the marker genotype relative frequencies, but, provided both parents and the sibs are genotyped, they are independent of the genotype frequencies. The proportion of marker alleles that a sib pair shares IBD, π (which in fact can take on only the values 0, 1/2, or 1), can then be estimated by $\hat{\pi} = \hat{f}_2 + (1/2)\hat{f}_1$. The values of $\hat{\pi}$ for different pairs of sibs in a sibship of more than two members are pairwise independent [13, 14].

Kruglyak and Lander [15] showed how the IBD allele-sharing probabilities can be estimated in a multipoint fashion with greater accuracy at each marker location and how they can be estimated at any intervening point along the genome. The algorithm has been implemented in the computer program package MAPMAKER/SIBS. The computational burden for exact multipoint IBD calculation is considerable even in nuclear families. The computation of the Elston–Stewart [16] algorithm increases exponentially with the markers. For the Lander–Green hidden Markov model used in Kruglyak *et al.* [17] to estimate the multipoint IBD, the computation increases exponentially with the number of nonfounders in a pedigree.

Fulker *et al.* [18] derived an alternative multipoint approximation algorithm for estimating π_Q , the proportion of the alleles IBD at any location Q for a pair of siblings, from the single point estimates of IBD at a set of m marker loci on the same chromosome. Their method is based on a multiple linear regression of π_Q on the m estimates $\hat{\pi}_1, \hat{\pi}_2, \dots, \hat{\pi}_m$ for m marker loci, using the fact that for any two loci i and j with recombination fraction θ_{ij} between them, $E[\text{Cov}(\hat{\pi}_i, \hat{\pi}_j)] = 8V(\hat{\pi}_i)V(\hat{\pi}_j)(1 - 2\theta_{ij})^2$. Their regression equation provides multipoint estimates of π_Q at any location Q other than the locations for which marker information is available; the estimates at those locations are the m

estimates themselves. The method has been shown to be as effective as MLE of the exact multipoint IBD distribution [19].

Almasy and Blangero [20] extended the sib-pair multipoint mapping approach of Fulker *et al.* [18] to general relative pairs, which allows multipoint analysis in pedigrees of unlimited size and complexity. This multipoint IBD method uses the proportion of alleles shared IBD at genotyped loci to estimate IBD sharing at arbitrary point along a chromosome for each relative pair. They derived correlations in IBD sharing as a function of chromosomal distance for relative pairs in general pedigree and provided a simple framework whereby these correlations can be easily obtained for any relative pair by a single line of descent or by multiple independent lines of descent. The multipoint algorithm has been implemented in the software SOLAR.

Model-Free Analysis of Qualitative Traits

The principal advantage of IBD-sharing model-free methods is that one does not need to specify, *a priori*, a detailed inheritance model for the trait of interest, which is often unknown for complex phenotypes of interest. We now present some examples of IBD-based model-free analysis of linkage for qualitative traits.

Mean Test for Affected Sib Pairs (ASP)

The data for affected sib-pair (ASP) methods are the frequencies with which two affected offspring share copies of the same parental marker allele IBD. Under the hypothesis of no linkage between a trait locus and a marker locus, it is expected that the probabilities of sharing 0, 1, or 2 alleles IBD are 0.25, 0.5, and 0.25, respectively. If there are two affected siblings in each family, let N be the total number of affected sib pairs and T be the total number of alleles shared by the N sib pairs IBD. Then the *mean test* is based on the mean proportion of marker alleles shared IBD by the ASP:

$$Z = \frac{(T - N)}{\sqrt{\frac{N}{2}}} \quad (11)$$

which approximately has a standard normal distribution $N(0, 1)$ for large N . The mean test is more

powerful than many alternative tests based on IBD sharing as found in [14]. Interestingly, for ASP data, for recessive disease mode, Knapp *et al.* [21] proved that the one-sided mean test is the uniformly most powerful test assuming no LD.

A Maximum LOD Score Method

A maximum LOD score (MLS) method was introduced by Risch [22] for assessing the significance of linkage based on IBD sharing. Let α_i be the prior probability that two relatives share i alleles IBD, Z_i be the posterior probability that two relatives share i marker alleles IBD given that they are both affected ($i = 0, 1, 2$) (i.e., $Z_i = P(\text{IBD}_m = i | \text{both affected})$), and let w_{ij} be the probability of the observed marker data of the j th pair (and possibly other relevant relatives) given that they share i marker alleles IBD, $i = 0, 1, 2$. That is $w_{ij} = P(\text{marker data of the } j\text{th pair} | \text{IBD}_m = i)$. The likelihood for the observed data on the j th pair is $L_j = \sum_{i=0}^2 Z_i w_{ij}$. Then the likelihood ratio for the N independent pairs is given by $\Lambda = \prod_{j=1}^N (\sum_{i=0}^2 Z_i w_{ij}) / (\sum_{i=0}^2 \alpha_i w_{ij})$. Then $T = \log_{10} \Lambda$ can be interpreted as an LOD score. The MLS can be obtained by maximizing with respect to Z_i , $i = 0, 1, 2$. Analogous to the criterion of an MLS > 3 in model-based linkage analysis [3], the same criterion may be applied to $T = \log_{10} \Lambda$.

The above MLS method is based on IBD sharing and is thus model-free, but it can be parameterized in terms of the proportion of marker alleles shared IBD, making them amenable to likelihood-type analysis. Next we present another model-free method, which is also in the form of an LRT.

Linkage Analysis Using Both IBD and LD

When a disease mutation arises in a population, the mutant allele is in LD with other alleles. The LD is attenuated in successive generations owing to recombinations, but this happens very slowly for loci that are very close to the disease locus. With the numerous genetic markers (e.g., the single nucleotide polymorphisms (SNPs)) that are densely spread along the genome currently available, some markers are likely to be very close to the disease locus and thus exhibit LD that may be used for fine mapping. However, allelic association might be due to population admixture, which can be a confounding factor for

gene mapping [23]. One way to overcome population admixture is to type markers on individuals with disease and their two parents to determine whether particular parental alleles are more often transmitted to the affected offspring rather than not transmitted, which is called the *transmission/disequilibrium test* (TDT) [24]. In essence, the linkage tests based on IBD sharing (e.g., the mean test) use recombination information in the current pedigree, whereas the linkage tests based on LD (e.g., the TDT) utilize historical recombination information. It is natural to consider combining these two approaches and utilizing both sources of recombination information. To this end, a marginal likelihood approach based on transmission of marker alleles has been developed recently in [25–27]. The method extends the maximum-binomial likelihood method of [28], which was designed to use all affected siblings for linkage analysis in a natural way. For the special case of affected sib-pair data, the score test of the marginal likelihood is the mean test in the absence of LD, and is the sum of the mean test and the TDT in the presence of LD. This method has better power than the mean test in the presence of strong LD, and has better power than the TDT when LD is weak. Thus it has good power regardless of the level of LD, which is good because LD is typically unknown and quite variable along the genome. This method is a valid model-free linkage test while some people have argued that the TDT is not a valid linkage test for various reasons, including that it has no power in the absence of LD.

Analysis of Quantitative Traits

Many traits such as height, blood pressure, glucose levels, and cholesterol levels can be quantified, with the resulting measurements being distributed in a continuous fashion across a population. Practical applications of quantitative-trait linkage analysis are increasing rapidly because of the superior information content of quantitative traits. Traditionally, the linkage analysis for general quantitative traits have been done using the regression approach of Haseman and Elston [11] based on IBD sharing of sib pairs. When trait values have an approximate normal distribution, the variance-component method is very useful and can use IBD sharing of general pedigrees [20]. Next we give an overview of both approaches.

Haseman–Elston Regression Methods and Extensions

The idea of the method proposed by Haseman and Elston [11] was to take pairs of siblings and regress the squared differences in their trait values on their IBD sharing at a marker. More precisely, let the i th sibling pair have trait values $(Y_{i,1}, Y_{i,2})$, and define the squared trait difference as $\hat{Y}_i^D = (Y_{i,1} - Y_{i,2})^2$. Summarize the estimated mean IBD sharing at the locus for the pair as $\hat{\pi}_i$. Perform a simple linear regression of $\hat{Y}_i^D$ on $\hat{\pi}_i$ using least squares. Under the null hypothesis of no linkage, the regression slope is zero. Under the alternative hypothesis that the locus is linked to the trait, high proportions of IBD sharing (large $\hat{\pi}_i$) should be associated with a small difference in trait values (small $\hat{Y}_i^D$). Because of this expected negative correlation between $\hat{Y}_i^D$ and $\hat{\pi}_i$, the regression slope is negative. Linkage can be tested with a one-sided t test of the regression slope estimate using the least-squares method. For example, assume a single quantitative trait locus (QTL) with two alleles Q and q . For an observed trait value Y , the genetic model may be written as follows:

$$Y = \mu + \gamma + e \quad (12)$$

where μ is an overall mean, γ is the effect of the QTL, and e is a residual effect. Suppose the two alleles Q and q have frequencies p_Q and $(1 - p_Q)$, respectively. The genotype-specific means of the trait are

$$\mu_{QQ} = \mu + a, \quad \mu_{Qq} = \mu + d, \quad \mu_{qq} = \mu - a \quad (13)$$

The total genetic variance is σ_γ^2 , which can be decomposed into two parts corresponding to additive effect and dominant effect, $\sigma_\gamma^2 = \sigma_a^2 + \sigma_d^2$, where the variances of the additive effect is $\sigma_a^2 = 2p_Q(1 - p_Q)[a + (1 - 2p_Q)d]^2$, and the variance of the dominant effect is $\sigma_d^2 = [2p_Q(1 - p_Q)d]^2$. Let θ denote the recombination fraction of the QTL and marker loci. Haseman and Elston [11] showed that for the special case of nondominance (i.e., only additive genetic variance) at the trait loci,

$$E(\hat{Y}^D | I_m) = \alpha_s + \beta_s \hat{\pi}_i \quad (14)$$

where $\beta_s = -2(1 - \theta)\sigma_\gamma^2$. It is clear that when $\theta = 0.5$, or $\sigma_\gamma = 0$, then $\beta_s = 0$; otherwise, $\beta_s < 0$. Thus, a one-sided test of linkage can be used. Several

research groups [29–35] have proposed approaches for improving the power of this regression method by use of information in both the squared trait difference $\hat{Y}_i^D$ and the squared trait sum $\hat{Y}_i^S = (Y_{i,1} + Y_{i,2})^2$. In particular, Wright [29] pointed out that Haseman and Elston's choice of $\hat{Y}_i^D$ discards some useful trait information contained in $\hat{Y}_i^S$. Drigalenko [30] showed that regression of $\hat{Y}_i^D$ on $\hat{\pi}_i$ and $\hat{Y}_i^S$ on $\hat{\pi}_i$ produces separate estimates of the same slope. Using average of the two resulting slope estimates is shown [30] to be equivalent to performing a single regression using the mean-corrected trait product, $\hat{Y}_i^P = [(Y_{i,1} - \mu)(Y_{i,2} - \mu)]$, as the dependent variable. Elston *et al.* [31] further developed the idea of regression based on $\hat{Y}_i^P$ and expanded it to consider larger sibships, covariates, and other complexities. Xu *et al.* [32], Forrest [33], and Sham and Purcell [34] suggested to improve the power of this regression method using different weighting of the two slope estimates. Visscher and Hopper [35] suggested using a combination of $\hat{Y}_i^D$, $\hat{Y}_i^S$ and the trait correlation between the pair of siblings as response variable and regressing on $\hat{\pi}_i$. Others have proposed score statistics to improve the power of this regression method [36–38].

All these methods are largely limited to sibships. Sham *et al.* [39] offered a regression method for general pedigrees. The idea is to reverse the Haseman–Elston paradigm by regressing the IBD sharing on an appropriate function of the quantitative-trait values. The actual regression that is suggested is a multivariate (not multiple) regression, within each family, of the pairwise IBD sharing scores on the pairwise squared sums and squared differences. This method is computationally manageable and has been implemented in the software package called *Merlin* [40]. Feingold [41] provides an excellent overview of regression-based QTL mapping methods.

Variance-Component Methods and Extensions

An alternative approach that simultaneously examines all pedigree relationships has also been developed from the classical variance-component analysis. The classical technique simply separates the total variance in the trait values into components due to genetic and environment effects [42]. Hopper and Matthews [43] first suggested adapting the method to linkage analysis by modeling an additional variance component

for a hypothesized QTL near a marker locus. Linkage to the locus is indicated by a statistically significant nonzero value for the QTL component. The earliest version of this method was based on analysis of only one or two markers at a time [44–46]. Goldgar [44] proposed a variance-component approach for analyzing nonexperimental sibships. Amos [46] developed a mixed-effects variance-component model for evaluating covariate effects, as well as evidence for genetic linkage to a single trait-affecting locus for pedigree data. Almasy and Blangero [20] improved on this approach by extending the approach to arbitrary pedigree and using an approximation to a multipoint algorithm.

Let the quantitative phenotypic value, Y , of an individual be written as a linear function of the n QTLs that influence it:

$$Y = \mu + \sum_{i=1}^n \gamma_i + e \quad (15)$$

where μ is the grand mean, γ_i is the random effect of the i th QTL, and e represents a random environmental effect. Assume $\{\gamma_i\}$ and e are uncorrelated with mean zero and so that the variance of Y is

$$\sigma_y^2 = \sum_{i=1}^n \sigma_{\gamma_i}^2 + \sigma_e^2 \quad (16)$$

When one allows for both additive and dominate effects, $\sigma_{\gamma_i}^2 = \sigma_{ai}^2 + \sigma_{di}^2$, where σ_{ai}^2 is the additive genetic variance due to the i th locus, and σ_{di}^2 is the dominance variance.

The covariance between the phenotype of different individuals $\{Y_j\}$ depends on the relatedness and the pedigree structure. It is determined by the IBD-sharing probabilities and the component variances σ_{ai}^2 and σ_{di}^2 . For the above random-effects model, the phenotypic covariance between the trait values of any pair of relative can be obtained as

$$\begin{aligned} \text{Cov}(Y_1, Y_2) &= E(Y_1 - \mu)(Y_2 - \mu) \\ &= \sum_{i=1}^n \left[\left(\frac{k_{1i}}{2 + k_{2i}} \right) \sigma_{ai}^2 + k_{2i} \sigma_{di}^2 \right] \end{aligned} \quad (17)$$

where k_{ji} is the i th QTL-specific probability of the pair of relatives sharing j alleles IBD. Let $\hat{\pi}_i = (k_{1i}/2 + k_{2i})$ be the coefficient of relationship or the probability of a random allele being shared IBD

at the i th QTL. When $n = 1$, the above model is reduced to the simple model in equation (12). The $\hat{\pi}_i$ and k_{2i} coefficients and their expectations effectively structure the expected phenotypic variance, and are the basis for much of the quantitative linkage analysis just as in the sib-pair difference method of Haseman and Elston [11] discussed above. For any given chromosomal location, $\hat{\pi}_i$ and k_{2i} coefficients can be estimated from genetic marker data I_m , e.g., using the software SOLAR developed in [20] or other software. By assuming multivariate normality as a working model for the trait distribution within pedigrees, the pedigree likelihood can be easily written down, which is totally determined by the mean and the covariance parameters. Numerical algorithms can be used to estimate the variance-component parameters. The likelihood-ratio test or the LOD scores can be used to test for linkage [20].

Frequently, only a few QTLs are examined at a time, and one can reduce the number of parameters in equation (15) that are to be considered. Let $\phi = (1/2)E(k_{1i}/2 + k_{2i})$ denote the expected kinship coefficient over the genome with $2\phi = R$ giving the expected coefficient of relation, and $\delta_\tau = E[k_{2i}]$ denote the expected probability of sharing two alleles IBD. Using 2ϕ to approximate $(k_{1i}/2 + k_{2i})$ and δ_τ for k_{2i} yields an approximation of the $\text{Cov}(Y_1, Y_2)$ as follows:

$$\text{Cov}(Y_1, Y_2) \approx 2\phi \sum_{i=1}^n \sigma_{ai}^2 + \delta_\tau \sum_{i=1}^n \sigma_{di}^2 \quad (18)$$

For example, if one is focusing on the analysis of the i th QTL in equation (15), one can absorb the effects of all other remaining QTLs in one random effect Γ_i term at unlinked loci. Then the expected phenotypic covariance between relatives is well approximated by

$$\text{Cov}(Y_1, Y_2) = \hat{\pi}_i \sigma_{ai}^2 + k_{2i} \sigma_{di}^2 + 2\phi \sigma_\Gamma^2 + \delta_\tau \sigma_d^2 \quad (19)$$

where σ_Γ^2 represents the additive genetic variance besides that of the i th QTL of interest, and σ_d^2 represents the residual dominant genetic variance. One can further replace μ by $\mu + \beta^T \mathbf{X}$, i.e., adding a fixed effect term to incorporate covariates, where $\mathbf{X}$ is a vector of directly observable covariates and β is a vector of regression coefficients. Then the mixed-effects model for the phenotypic value can be written as

$$Y = \beta^T \mathbf{X} + \gamma + \Gamma + e \quad (20)$$

This model includes covariates fixed effect, a major gene effect, random polygenic effects, and random environmental effects. This variance-component-based model can be used for mapping QTL in general human pedigrees and has good power when the trait values have an approximate normal distribution. This variance-component approach has also been extended by de Andrade *et al.* [47] to the context of longitudinal studies where quantitative traits are measured repeatedly over time, such as in the Framingham Heart Study [48]. For such data, in addition to the correlation among pedigree members, there is also within-subject correlation among the repeated measures of the same individual over time.

A practical concern of the variance-component approach is the robustness with respect to the normality assumption for the trait values. Violation of the normality assumption might have serious adverse effects on both type I errors and power [49–51]. In this case, the variance-component approach is less robust than Haseman–Elston regression method [52] and the distribution-free method suggested in [15]. One might consider using generalized estimating equations for estimating variance components [46, 49]. Another natural strategy is to perform a parametric transformation $H(\cdot)$, such as the log-transformation or square-root transformation on the trait values to approximate normality [48, 52, 53]. However, it can be hard to find a generally useful parametric transformation, and different transformations might lead to conflicting results.

Diao and Lin [54] proposed a novel extension of the above variance-component model that allows the true transformation function $H(\cdot)$ to be completely unspecified:

$$H(Y) = \beta^T \mathbf{X} + \gamma + \Gamma + e \quad (21)$$

Diao and Lin [54] also present efficient likelihood-based procedures to estimate variance components and to test for genetic linkage. The method allows choice of software to estimate the multipoint IBD allele-sharing probabilities. Thus one may choose appropriate software according to the size and complexity of the pedigrees as well as the number of markers. GENEHUNTER [17] and ACT [46] perform multipoint calculation that are based on hidden Markov models [55] and can handle an arbitrary number of markers for small pedigrees, whereas the approximation method implemented in SOLAR [20]

can handle large pedigrees. The above semiparametric transformation model for variance component in equation (21) provides great flexibility on the trait distribution. However, it still requires that the phenotype is fully observed and has a known distribution after some unknown transformation. These assumptions may not be satisfied when the phenotype pertains to the survival time or age of onset, which has a skewed distribution and is usually subject to censoring due to random loss of follow-up or limited duration of the experiment. In addition, the QTL may only affect the survival of a latent subpopulation. An extension to censored trait data is given in [56] for human pedigrees. For experimental crosses, semiparametric survival methods using Cox's regression model for interval mapping of QTL with time-to-event phenotypes under random censoring have also been developed in [57, 58], and others.

Discussion

With the wide range of methodologies currently available, it is natural to ask which method should be used for the given data. There is no simple answer to this question. Choice of methods may depend on many considerations including the statistical design, size and complexity of the pedigrees, the phenotypes (qualitative or quantitative), current knowledge of the pattern of trait inheritance, etc. In general, the desirable characteristics of a good linkage analysis method may include high statistical power, correct significance level (validity), and certain robustness [4, 41].

In terms of statistical power, likelihood-based analysis is the benchmark when the genetic model is correctly specified. The nonparametric methods (e.g., using score tests) are often designed to emulate this power optimality. On the other hand, the model-free methods are often relatively easy to compute besides being more robust than parametric methods.

Determining appropriate genome-wide significant levels is critical for whole genome scans, which are becoming the commonly used designs [59, 60]. Using liberal genome-wide significance levels can lead to an abundance of false discoveries whereas using overly conservative levels would diminish the statistical power and lead to many lost opportunities. Much progress has been made in developing useful statistical methods to evaluate genome-wide significance levels. These include using maximums of the

Gaussian process as in Lander and Botstein [61] for mapping QTL in a backcross design and as in Feingold *et al.* [62] for human genetics with IBD-sharing statistics. Lin [63] discussed a resampling (or random weighting) scheme that is useful for finding genome-wide significance levels for a general class of score-type test statistics, which can be used in a variety of genome-wide studies.

In terms of effective sampling designs for genome scan, Elston [64] and Elston *et al.* [65] proposed a two-stage procedure in which at the first stage affected pairs of relatives are typed for widely spaced markers and a relatively large significance level is used to determine where, at a second stage, more narrowly spaced markers should be placed around the markers that were significant at the first stage. Statistical efficiency is gained because a tight grid of markers is typed only at locations presenting evidence that a trait locus might occur. Further developments can be found in [60, 66].

Motivated by mapping complex traits, and spurred by the recent successes of various genome projects and rapid advancements of biotechnology, enormous progress in developing new linkage analysis methods has been made, which remains an active area of current research. Owing to page limitations, this article provides a very brief overview of the likelihood-based (LOD score) parametric methods and the nonparametric methods based on IBD sharing. For in-depth overviews of many other aspects of linkage analysis, interested readers may consult the classical textbook by Ott [1], and a large collection of excellent overview articles contained in Volume 42 of *Advance in Genetics* (2001).

Logistic Regression

A common question faced by researchers in epidemiologic studies is whether a particular exposure (or exposures) is causally related to (*see* **Causality/Causation**) an outcome or disease process. In many studies, the outcome is a dichotomous variable – a variable that can be assigned one of two possible values, for example, presence/absence of disease or occurrence/nonoccurrence of an event. Logistic regression is the most commonly used statistical tool to answer such questions, especially, when the outcome is dichotomous. In this chapter, we describe the logistic model, explain estimation of the *odds ratio* (OR) (*see* **Odds and Odds Ratio**) using logistic regression, describe hypothesis testing and confidence interval (CI) estimation in the logistic regression framework, and finally, illustrate the use of logistic regression using data from an epidemiologic study.

The Logistic Model

The logistic regression model belongs to a family of statistical models known as *generalized linear models*. Logistic regression can be used to describe the relationship of several predictor/independent variables (usually denoted by $X_1, X_2, \dots, X_k$) to a dichotomous outcome/dependent variable (denoted by Y), which is typically coded as 1 or 0 for the two possible values that it can take. The logistic model, as shown in equation (1) below, describes the expected value of Y (denoted by $E(Y)$):

$$E(Y) = \frac{1}{1 + \exp \left[- \left(\beta_0 + \sum_{j=1}^k \beta_j X_j \right) \right]} \quad (1)$$

where $E(Y)$ is equivalent to the probability $\Pr(Y = 1)$ for the (0, 1) random variable Y , β_0 is the intercept in the model, and the β_j 's are the slope parameters for the independent X_j 's.

There are three broad steps involved in logistic regression analysis:

1. We first postulate a mathematical model on the basis of prior knowledge about and experience with the outcome under study that describes the

mean of outcome Y as a function of the independent variables X_j and their slope parameters β_j .

2. We then fit the model to the data obtained from the epidemiologic study using maximum likelihood (ML) procedures that enable us to estimate the model parameters (the β_0 and the β_j).
3. Finally, after assessing the fit of the model and relevant regression diagnostic indices, we make appropriate statistical inferences about measures of effect (typically *ORs*) that are derived from estimated model parameters.

There are two reasons for the popularity of the logistic model. Both reasons relate to the mathematical expression on the right side of the logistic regression formula in equation (1). It is evident that the right side expression in equation (1) is of the general mathematical form given in equation (2):

$$f(z) = \frac{1}{1 + e^{-z}} \quad (2)$$

where

$$z = \left(\beta_0 + \sum_{j=1}^k \beta_j X_j \right) \quad (3)$$

The function $f(z)$ is called the *logistic function*. The values of $f(z)$ range from 0 to 1 as z varies from $-\infty$ to $+\infty$. This property makes the logistic function very useful to model probability, and in epidemiologic studies, such a probability can be used to describe an individual's risk of getting the outcome.

Another reason for the popularity of the logistic function relates to its general shape as shown in Figure 1. A plot of the logistic function is in the form of a sigmoid curve which epidemiologists believe applies to a variety of disease conditions. In this context, the variable z can be thought of as a combination of various risk factors (the X_j), so that $f(z)$ represents the risk of the outcome for a given value of z . As seen from the figure, the risk is near zero for low z values, rises over a range of intermediate z values, and remains close to 1 once z gets large enough.

Figure 1 The shape of the logistic function $f(z) = \frac{1}{1+e^{-z}}$. Kleinbaum *et al.* [1] [From Applied Regression Analysis and Multivariable Methods 3rd edition by KLEINBAUM/KUUPER/MULLER/NIZAM, 1998. Estimating the Odds Ratio Using Logistic Regression

The purpose of regression models is to provide us with estimates of model parameters that can then be used to describe the relationship between the outcome variable (Y) and one or more predictors (X 's). Some of these predictors, often called *exposure variables* are of primary interest, whereas other predictors, often called *control variables* are not of primary interest, but are, nevertheless, considered in one's model to control for their possible effects on the outcome (see **Confounding**).

For the logistic regression model, quantification of these relationships typically involves a measure of effect known as the *odds ratio* (see **Odds and Odds Ratio**) that is derived from the parameter estimates. Briefly, an odds can be defined as the ratio of the probability of some event occurring to the probability of that event not occurring. An *OR*, by definition, is a ratio of two odds. For example, let us consider an epidemiologic study evaluating the occurrence of disease D in two groups of individuals A and B , one with and the other without an exposure of interest. Let $A = E$ denote the group with exposure E and $B = NE$ denote the group without the exposure E ; then D_E describes persons with exposure E that develop D and D_{NE} describes persons without exposure E that develop D . If $\Pr(D_E) = 0.25$ and $\Pr(D_{NE}) = 0.10$, the *OR* that compares the odds of developing disease D for those with exposure E with the odds of developing D for those without exposure E is given

by equation (4):

$$\begin{aligned} OR_{E \text{ vs } NE} &= \frac{\text{odds}(D_E)}{\text{odds}(D_{NE})} = \frac{\frac{\Pr(D_E)}{1 - \Pr(D_E)}}{\frac{\Pr(D_{NE})}{1 - \Pr(D_{NE})}} \\ &= \frac{0.25}{\frac{1 - 0.25}{0.10}} = \frac{1/3}{1/9} = 3 \end{aligned} \quad (4)$$

In other words, the odds of developing disease D in those with exposure E is three times the corresponding odds for those without exposure E , suggesting roughly that those with E have a threefold higher risk of developing D than those without E . An *OR* of one would mean that the odds for the two groups are the same; that is, exposure E does not affect the development of disease D .

Why is the *OR* the measure of effect when we do logistic regression analysis? To answer this question, let us consider another way of describing the logistic regression model, called the *logit form* of the model. The *logit* term is defined as the natural log odds of the event ($Y = 1$), and can be thought of as a transformation of the probability $\Pr(Y = 1)$. We can thus present the logistic model as shown in equation (5): E vs NE

$$\begin{aligned} \text{logit}[\Pr(Y = 1)] &= \log_e[\text{odds}(Y = 1)] \\ &= \log_e \left[\frac{\Pr(Y = 1)}{1 - \Pr(Y = 1)} \right] \end{aligned} \quad (5)$$

If we then substitute the logistic model formula (equation (1)) for $\Pr(Y = 1)$ into equation (5), it follows that

$$\text{logit}[\Pr(Y = 1)] = \beta_0 + \sum_{j=1}^k \beta_j X_j \quad (6)$$

Equation (6) is called the *logit form* of the model. An attractive quality of the logit form is that it expresses the model as a linear combination of the independent variables and their parameters.

For example, if Y denotes disease D status (1 = yes, 0 = no) and there is only one (i.e., $k = 1$) predictor X_1 – say, exposure to E (1 = exposed to E , 0 = not exposed to E) – then the logistic model in logit form can be written as

$$\text{logit}[\Pr(Y = 1)] = \beta_0 + \beta_1 X_1 = \beta_0 + \beta_1 E \quad (7)$$

To obtain an expression for the *OR* from a logistic model, we must compare the odds for two groups of individuals. For the example given above involving only one independent variable, the two groups are those exposed to E (i.e., $E = 1$) and those not exposed to E (i.e., $E = 0$). The log odds for these two groups can be written as

$$\log_e \text{odds}(\text{exposed to } E) = \beta_0 + (\beta_1 \times 1) = \beta_0 + \beta_1 \quad (8)$$

and

$$\log_e \text{odds}(\text{not exposed to } E) = \beta_0 + (\beta_1 \times 0) = \beta_0 \quad (9)$$

It follows that the *OR* comparing exposed to unexposed is given by the following formula:

$$\begin{aligned} OR_{E \text{ vs } NE} &= \frac{\text{odds}(\text{exposed to } E)}{\text{odds}(\text{not exposed to } E)} \\ &= \frac{\exp(\beta_0 + \beta_1)}{\exp(\beta_0)} = \exp(\beta_1) \end{aligned} \quad (10)$$

In other words, for the simple example involving one (0, 1) predictor, the *OR* comparing the two categories of the predictor is obtained by exponentiating the coefficient of the predictor in the logistic model, as shown in equation (10).

Generally, when computing an *OR*, we can define two groups (or individuals) that are to be compared in terms of two different specifications of the set of predictors ($X_1, X_2, \dots, X_k$). For example, let $\mathbf{X}_A = (X_{A1}, X_{A2}, \dots, X_{Ak})$ and $\mathbf{X}_B = (X_{B1}, X_{B2}, \dots, X_{Bk})$ denote the collection of X 's for groups (or individuals) A and B , respectively. On the basis of the logit form of the model shown in equation (6), the log odds for the two groups are

$$\log_e \text{odds for } \mathbf{X}_A = \beta_0 + \sum_{j=1}^k \beta_j X_{Aj} \quad (11)$$

and

$$\log_e \text{odds for } \mathbf{X}_B = \beta_0 + \sum_{j=1}^k \beta_j X_{Bj} \quad (12)$$

To obtain a general formula for the *OR*, we must divide the odds for group (or individual) A by the odds for group (or individual) B , which gives

us an expression involving the logistic regression parameters. Equation (13) shows the general *OR* formula:

$$\begin{aligned} OR_{X_A \text{ vs } X_B} &= \frac{\text{odds for } X_A}{\text{odds for } X_B} \\ &= \frac{\exp\left(\beta_0 + \sum_{j=1}^k \beta_j X_{Aj}\right)}{\exp\left(\beta_0 + \sum_{j=1}^k \beta_j X_{Bj}\right)} \\ &= \exp \sum_{j=1}^k \beta_j (X_{Aj} - X_{Bj}) \end{aligned} \quad (13)$$

The constant term β_0 in the logistic model (equation (1)) drops out of the *OR* expression (equation (13)), so the *OR* depends only on exponentiating the sum of the β_j coefficients multiplied by the difference in corresponding values of the X_j 's for groups (or individuals) A and B .

Equation (13) describes a “population” *OR* parameter because the β_j terms in this expression are themselves unknown population parameters. An estimate of this population *OR* can be obtained by fitting the logistic model using *ML* estimation and substituting the *ML* parameter estimates $\hat{\beta}_j$ (note the $\hat{\cdot}$ on β_j that is used to denote an estimated value of the unknown population parameter), together with values of X_{Aj} and X_{Bj} , into the formula shown in equation (13) to obtain a numerical value that estimates the *OR*.

In general, when the logistic model involves more than one independent (X_j) variable and only one variable (i.e., the exposure variable) changes, while the other (i.e., control) variables are held constant, we say that the *OR* comparing two categories of the changing variable is an *adjusted OR* that controls for the other variables in the model. When the exposure variable is a (0, 1) variable and there are no product terms involving the exposure variable and other (control) variable(s) in the model, equation (13) simplifies to the following:

$$OR_{X_A \text{ vs } X_B} = \exp(\beta_j(1 - 0)) = \exp(\beta_j) \quad (14)$$

where β_j is the exposure variable of interest. However, if the exposure variable is not a (0, 1) variable and/or there are product terms in the model involving the exposure variable (referred to as *interaction*

terms or effect modifiers – see **Effect Modification and Interaction**), then we cannot use equation (14) to get an estimate for the *OR*. In such situations, we use the general formula shown in equation (13) to obtain the *OR* estimate(s).

Hypothesis Testing and Confidence Interval Estimation

The estimated *OR* calculated above is known as the *point estimate* of the unknown population parameter – the true *OR*. Such point estimates have a certain amount of variability associated with them, as represented by the standard error estimates of the coefficients. This variability has to be considered when we make statistical inference on the parameters of interest. We can use two kinds of inference-making procedures. One is testing hypothesis about certain parameters, the other is deriving interval estimates of certain parameters.

Statistical inference-making requires three quantities, which can be readily obtained by the default output provided by most *ML* estimation programs in most statistical software bundles. These are the *maximized likelihood value*, the *estimated variance-covariance matrix* and a *listing of each variable followed by its ML estimate and standard error*. To illustrate how statistical inferences are made using these quantities, we consider two logit models, as shown in equations (15) and (16):

Model 1:

$$\text{logit}[\text{Pr}(Y = 1)] = \beta_0 + \beta_1 X_1 + \beta_2 X_2 \quad (15)$$

Model 2:

$$\text{logit}[\text{Pr}(Y = 1)] = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 \quad (16)$$

There are two commonly used tests for testing hypothesis in logistic regression – the *likelihood ratio (LR) test* and the *Wald test*. The *LR* test is a comparison of the log likelihood statistic (defined as $-2 \log_e$ of the maximized likelihood value) of the two models that are being compared. The test statistic, called the *LR statistic*, is the difference between the log likelihood statistics of the two models being compared, one of which is a subset of the other (for example, model 1 above is a subset of model 2). The larger model is referred to as the *full model* and the smaller as the *reduced model*; that is, the reduced

model is obtained by setting certain parameters in the full model to zero. For example, setting β_3 to zero in model 2 would reduce it to model 1; thus, model 1 is the reduced model and model 2 is the full model. The *LR* statistic in large samples has an approximate χ^2 distribution and the degrees of freedom (df) for this χ^2 test are equal to the difference between the number of parameters in the two models.

Let us now compare model 1 with model 2 as an example of the *LR* test. The additional parameter in the full model (model 2) that is not part of the reduced model (model 1) is β_3 , the coefficient of the variable X_3 . Thus, the null hypothesis that compares Models 1 and 2 is stated as β_3 equal to 0 (usually denoted as $H_0 : \beta_3 = 0$). If we suppose that X_3 is a (0, 1) exposure variable and X_1 and X_2 are confounders, then the *OR* for the exposure–disease relationship controlling for confounders is given by $\exp(\beta_3)$. Thus, in this case, testing the null hypothesis that $\beta_3 = 0$ is equivalent to testing the null hypothesis that the adjusted *OR* for effect of exposure is equal to $\exp(0) = 1$ (i.e., the null value for *OR* is therefore 1 and not 0).

To test this null hypothesis, the corresponding *LR* statistic is given by the following quantity:

$$\begin{aligned} \text{LR statistic} &= (-2 \log_e L_1) - (-2 \log_e L_2) \\ &= -2 \log_e \left(\frac{L_1}{L_2} \right) \end{aligned} \quad (17)$$

where $L_1 = ML$ value for model 1 and, $L_2 = ML$ value for model 2.

The *LR* statistic is approximately χ^2 if the study size is large with $df = 1$, for this case. The *P* value associated with the *LR* statistic is then calculated using the χ^2 distribution with 1 *df* and we reject the null hypothesis if the *P* value is greater than the prefixed value of α (α is typically fixed at 0.05).

The *Wald test* is another way of carrying out hypothesis testing in logistic regression. This test is usually done when there is only one parameter being tested (for example, comparing models 1 and 2 above). The *Wald test* statistic is computed by dividing the estimated coefficient of interest by its standard error. This test statistic has approximately a normal or *Z* distribution in large samples. The square of this *Z* statistic is approximately a χ^2 statistic with 1 *df*. We can carry out the *Wald test* by looking up the *ML* coefficient of the parameter of interest and its standard error from the logistic regression output.

Several packages, including SAS, also compute the χ^2 statistic and the P value associated with it.

As an example of a Wald test, consider models 1 and 2. The Wald test for testing the null hypothesis that $\beta_3 = 0$ is given by the Z statistic which is equal to $\hat{\beta}_3$ divided by the standard error of $\hat{\beta}_3$. The computed Z can be compared to percentage points from a standard normal table or Z can be squared and then compared to percentage points from a χ^2 distribution with 1 *df*.

The LR statistic and its corresponding Wald statistic give approximately the same value in very large samples; so if the study is large enough, it will not matter which statistic is used. Nevertheless, the LR statistic is generally preferred over (i.e., has better statistical properties than) the Wald statistic whenever numerical values computed for corresponding LR and Wald statistics differ substantially.

The most commonly reported interval estimate is the large sample CI for the parameter obtained by computing the estimate of the parameter plus or minus a percentage point of the normal distribution times the estimated standard error. For example, the CI for the β_3 parameter in model 2 is given by

$$100(1 - \alpha)\% \text{ CI for } \beta_3 = \hat{\beta}_3 \pm Z_{1-\alpha/2} \times s_{\hat{\beta}_3} \quad (18)$$

where $s_{\hat{\beta}_3}$ = standard error of $\hat{\beta}_3$.

In the formula shown in equation (18), the values for $\hat{\beta}_3$ and its standard error estimate are obtained from the relevant computer output. The Z percentage point is obtained from tables of the standard normal distribution. For example, if we want a 95% CI , then $\alpha = 0.05$, $1 - \alpha/2 = 0.975$, and $Z_{0.975} = 1.96$. The formula for the 95% CI can then be represented as

$$95\% \text{ CI for } \beta_3 = \hat{\beta}_3 \pm 1.96 \times s_{\hat{\beta}_3} \quad (19)$$

However, most epidemiologists are more interested in the CI for an OR rather than the CI for the parameter coefficient. When we are considering only one (0, 1) exposure variable (for example, X_3 in model 2), then the CI for the OR is obtained by exponentiating the confidence limits obtained for the parameter:

$$\begin{aligned} 95\% \text{ CI for } OR &= 95\% \text{ CI for } \exp(\beta_3) \\ &= \exp(\hat{\beta}_3 \pm 1.96 \times s_{\hat{\beta}_3}) \quad (20) \end{aligned}$$

The formula in equation (20) is correct provided that the variable X_3 is a (0, 1) variable. If this variable

is coded differently (for example, as $(-1, 1)$) or if it is an ordinal or interval variable, then the CI formula must be modified to reflect the coding.

Equation (20) will help us obtain the lower and upper bounds on the OR . The width of the CI (upper bound minus lower bound) informs us about the precision of our point estimate, a wider interval indicating more uncertainty in the estimate as compared to a narrower interval. Additionally, the CI allows us to comment on the statistical significance of the obtained point estimate. If the null value of one (for the OR estimates) is included in the CI then we can conclude that the point estimate is not statistically significant.

In the following section we use a numerical example to illustrate the concepts outlined above.

Numerical Example of Logistic Regression

(From Applied Regression Analysis and Multivariable Methods 3rd edition by KLEINBAUM/KUPPER/MULLER/NIZAM. 1998. Reprinted with permission of Brooks/Cole, a division of Thomson learning: www.thomsonrights.com. Fax (800)730-2215).

Dengue fever is an acute viral fever transmitted by the *Aedes* mosquito. A retrospective survey of an epidemic of dengue fever was carried out in three Mexican cities in 1984 [2]. We will use a subset of the data obtained from this study that includes a random sample of 196 persons from the city of Puerto Vallarta, 57 of whom were determined to be suffering from dengue fever. The primary aim of the analysis was to identify risk factors associated with having the disease, especially the effect of use of mosquito netting as a determinant of the dengue fever. The analysis was carried out using the SAS statistical procedure. A description of the variables present in the dataset DENGUE.DAT ("The dataset DENGUE.DAT can be freely downloaded from the author's website using the following link <http://www.sph.emory.edu/~dkleinb/ar4.htm>") and used in the analysis is provided below:

Subject ID

Dengue fever status (DENGUE): 1 = yes, 2 = no
Age in years (AGE)

Use of mosquito netting (MOSNET): 0 = yes, 1 = no

Geographical sector in which the subject lived (SECTOR): 1-5

The variable SECTOR was treated as a categorical variable in the regression analysis, so we created four dummy variables to distinguish the five geographical sectors. Sector 5 was chosen as the referent group and the variables were defined as follows:

SECTOR1 = 1 if sector 1, 0 otherwise
 SECTOR2 = 1 if sector 2, 0 otherwise
 SECTOR3 = 1 if sector 3, 0 otherwise
 SECTOR4 = 1 if sector 4, 0 otherwise.

We fit the following logistic model, stated in logit form, to these data:

$$\begin{aligned} \text{logit}[\Pr(Y = 1)] = & \beta_0 + \beta_1(\text{AGE}) + \beta_2(\text{MOSNET}) \\ & + \beta_3(\text{SECTOR1}) + \beta_4(\text{SECTOR2}) \\ & + \beta_5(\text{SECTOR3}) + \beta_6(\text{SECTOR4}) \end{aligned} \quad (21)$$

where Y denotes the outcome variable DENGUE.

The relevant portion of the output obtained when we fit the logistic model using SAS software is shown in Table 1.

From Table 1, we can see that the *ML* coefficients (parameter estimates) obtained for the fitted model are

$$\begin{aligned} \hat{\beta}_0 &= -1.9001, \hat{\beta}_1 = 0.0243, \hat{\beta}_2 = 0.3335, \\ \hat{\beta}_3 &= -2.2200, \hat{\beta}_4 = -0.6589, \hat{\beta}_5 = 0.8121, \\ \hat{\beta}_6 &= 0.5310 \end{aligned} \quad (22)$$

so the fitted model is given in logit form by

$$\begin{aligned} \text{logit}[\hat{\Pr}(Y = 1)] \\ = & -1.9001 + 0.0243(\text{AGE}) + 0.3335(\text{MOSNET}) \\ & - 2.2200(\text{SECTOR1}) - 0.6589(\text{SECTOR2}) \\ & + 0.8121(\text{SECTOR3}) + 0.5310(\text{SECTOR4}) \end{aligned} \quad (23)$$

On the basis of this fitted model (with estimates obtained from the computer output), we can compute the estimated *OR* for contracting dengue fever for persons who did not use mosquito netting relative to persons who did use mosquito netting, controlling for age and sector. We can use the formula shown in equation (14) in this case because MOSNET is a (0, 1) variable and there are no product terms in the model. The estimated *OR* is thus obtained by exponentiating the estimated coefficient ($\hat{\beta}_2$) of the MOSNET variable in the fitted model, as shown below:

$$\begin{aligned} \hat{OR}_{(\text{MOSNET}=1 \text{ vs } \text{MOSNET}=0 | \text{age, sector})} \\ = \exp(\hat{\beta}_2) = \exp(0.3335) = 1.396 \end{aligned} \quad (24)$$

The estimated *OR* shown in equation (24) is the odds of getting dengue in those who do not use mosquito netting as compared to the odds in those who use it *given* we keep age and sector constant. So for this case, we are considering MOSNET as the exposure variable and AGE and SECTOR as confounders. From the estimated *OR*, we can conclude that the odds of contracting dengue is about 1.4 times higher for a person who did not use mosquito netting than for a person who did use mosquito netting while controlling for age and sector.

A 95% *CI* for the estimated *OR* in equation (24) above can be computed by using the formula in equation (20).

$$\begin{aligned} 95\% \text{ CI for } \hat{OR}_{(\text{MOSNET}=1 \text{ vs } \text{MOSNET}=0 | \text{age, sector})} \\ = \exp\left(\hat{\beta}_2 \pm 1.96 \times s_{\hat{\beta}_2}\right) \\ = \exp[0.3335 \pm 1.96(1.2718)] \end{aligned} \quad (25)$$

where 1.2718 is the estimated standard error of $\hat{\beta}_2$ (see Table 1). The resulting lower and upper confidence limits are 0.115 and 16.89, respectively.

Table 1 Maximum likelihood estimates obtained by fitting the logistic model shown in equation (15) using the LOGISTIC procedure in SAS

Parameter	Estimate	Standard error	Wald χ^2	Pr > χ^2	Odds ratio
Intercept	-1.9001	1.3254	2.0551	0.1517	0.150
AGE	0.0243	0.00906	7.1778	0.0074	1.025
MOSNET	0.3335	1.2718	0.0688	0.7931	1.396
SECTOR1	-2.2200	1.0723	4.2861	0.0384	0.109
SECTOR2	-0.6589	0.5536	1.4164	0.2340	0.517
SECTOR3	0.8121	0.4750	2.9235	0.0873	2.253
SECTOR4	0.5310	0.4502	1.3911	0.2382	1.701

We can see that the *CI* is very wide and contains the null value of one.

We can also conduct hypothesis testing by using Wald and *LR* tests to test the following null hypothesis:

$$H_0 : OR_{(MOSNET=1 \text{ vs } MOSNET=0 | \text{age, sector})} = 1 \quad (26)$$

or equivalently,

$$H_0 : \beta_2 = 0 \quad (27)$$

The Wald (χ^2) statistic for the null hypothesis and the corresponding *P* value are 0.0688 and 0.7931, respectively (see the row for parameter MOSNET in Table 1). The *P* value of 0.7931 being greater than $\alpha = 0.05$, we conclude that *OR* is not statistically significantly different from 1.

As stated earlier, the *LR* test can be conducted by fitting two models – the full and the reduced models. In this case, the full model is the same as shown in equation (21). The reduced model is obtained under the null hypothesis by dropping the exposure variable (MOSNET) from the full model. The reduced form can be written in the logit form as

$$\begin{aligned} \text{logit}[\Pr(Y = 1)] \\ = \beta_0 + \beta_1(\text{AGE}) + \beta_3(\text{SECTOR1}) \\ + \beta_4(\text{SECTOR2}) + \beta_5(\text{SECTOR3}) \\ + \beta_6(\text{SECTOR4}) \end{aligned} \quad (28)$$

We can obtain the respective log likelihoods for the two models from the computer output (not shown) generated by fitting these models. The $-2 \log_e L_F$ was 203.706 and that of the reduced model (denoted by $-2 \log_e L_R$) was 203.778. The *LR* statistic for these two models can be computed by using the formula shown in equation (17).

$$\begin{aligned} LR \text{ statistic} &= (-2 \log_e L_R) - (-2 \log_e L_F) \\ &= 203.778 - 203.706 = 0.072 \end{aligned} \quad (29)$$

This statistic is χ^2 with 1 *df* because the null hypothesis $H_0 : \beta_2 = 0$ involves only one parameter; the test is nonsignificant at the $\alpha = 0.05$ level. This agrees with our prior observations obtained from looking at the *CI* and the Wald test. These observations support the conclusion that there is no statistical evidence in these data that the nonuse of mosquito netting, significantly increases the probability (or risk) of contracting dengue fever.

We can also evaluate the effect of predictors other than MOSNET on the probability of getting dengue fever from the logistic model in equation (21), involving the predictors AGE, MOSNET, and SECTOR1 through SECTOR4. For example, let us examine the effect of AGE, controlling for MOSNET and the four SECTOR dummy variables. From the row corresponding to the parameter AGE in Table 1, we find that the Wald χ^2 statistic is 7.1778. The null hypothesis being tested here is

$$H_0 : \beta_1 = 0 \quad (30)$$

where β_1 is the coefficient of the AGE variable in the model shown in equation (21). The *P* value for this test is 0.0074 (see Table 1), so we can reject the null hypothesis (at $\alpha < 0.01$ significance level) and conclude that the AGE variable is a significant predictor of dengue fever status. In particular, the positive estimated coefficient for AGE suggests that the risk of dengue fever increases with increasing age.

The *LR* test of the same null hypothesis (i.e., $H_0 : \beta_1 = 0$) would require subtracting the log likelihood statistic for the full model (equation (21)) from the log likelihood statistic for the following reduced model, which is obtained by dropping the AGE variable from equation (21).

$$\begin{aligned} \text{logit}[\Pr(Y = 1)] \\ = \beta_0 + \beta_2(\text{MOSNET}) + \beta_3(\text{SECTOR1}) \\ + \beta_4(\text{SECTOR2}) + \beta_5(\text{SECTOR3}) \\ + \beta_6(\text{SECTOR4}) \end{aligned} \quad (31)$$

The resulting *LR* test also gives a significant result (data not shown), which is in concordance with the significant result obtained from the Wald test.

Since the (Wald or *LR*) test just described measures the effect of a continuous variable (AGE), its specific purpose is to assess whether the effect of the AGE variable in equation (21) is described by a significant linear relationship between AGE and the log odds of dengue fever, controlling for the other variables in the model. In other words, when no other functions of AGE (e.g., AGE² or AGE $\times$ MOSNET) other than AGE itself are in the model, then we are testing whether a linear effect in AGE is more plausible than no effect of age (i.e., we are testing $H_0 : \beta_1 = 0$) of AGE. Such a test is typically referred to as a (*linear*) *trend* test. Thus, using the

results shown in Table 1, we conclude that a linear trend test for AGE in equation (21) is significant.

Since the AGE variable is a continuous variable in the model in equation (21), the quantity $\exp(\hat{\beta}_1)$ is the following OR estimate:

$$\begin{aligned}\hat{OR}_{(AGE1-AGE0=1 \mid \text{mosnet, sector})} &= \exp(\hat{\beta}_1) \\ &= \exp(0.0.0243) = 1.025\end{aligned}\quad (32)$$

where $\hat{\beta}_1$ is the estimated coefficient of the AGE variable (see Table 1).

The estimated OR in equation (32) describes the OR comparing two persons whose age differs by only 1 year. Since AGE is continuous, a one-unit difference in AGE is rarely of interest. Instead, we need to compare meaningfully (e.g., clinically) different categories of AGE. For example, we might consider two persons whose ages differ by 5 years – say, a 35-year-old person and a 30-year-old person – as having a meaningful difference in age. Using the general OR expression shown in equation (13), we can compute the estimated OR for two persons with a 5-year age difference, controlling for mosquito netting and sector, as follows:

$$\begin{aligned}\hat{OR}_{(AGE1-AGE0=5 \mid \text{mosnet, sector})} &= \exp[5\hat{\beta}_1 + (\text{MOSNET} - \text{MOSNET})\hat{\beta}_2 \\ &\quad + (\text{SECTOR1} - \text{SECTOR1})\hat{\beta}_3 + \dots \\ &\quad + (\text{SECTOR4} - \text{SECTOR4})\hat{\beta}_6] \\ &= \exp[5\hat{\beta}_1] = \exp[5(0.0243)] = 1.13\end{aligned}\quad (33)$$

Since we are controlling for mosquito netting and sector status, we assume that the MOSNET variable has the same value, and that the four sector variables (SECTOR1 through SECTOR4) have the same value for the two persons being compared. The coefficients of these five variables then drop out of the OR expression, and we have only the quantity $5\hat{\beta}_1$ to exponentiate. The estimated adjusted OR is therefore given by $\exp[5\hat{\beta}_1]$ rather than by $\exp[\hat{\beta}_1]$, since we are considering the effect of a 5-year rather than a 1-year difference in age. Thus, for two persons whose age differs by 5 years, the adjusted OR that controls for use of mosquito netting and sector status equals 1.13, which is quite close to the null value of 1.

To obtain a 95% CI for this adjusted OR (i.e., $5\hat{\beta}_1$), we make the following calculation using

values obtained from Table 1:

$$\begin{aligned}95\% \text{ CI for } \hat{OR}_{(AGE1-AGE0=5 \mid \text{mosnet, sector})} : \\ &= \exp[5\hat{\beta}_1 \pm 1.96(5s_{\hat{\beta}_1})] \\ &= \exp[5(0.0.0243) \pm 1.96(5)(0.0091)]\end{aligned}\quad (34)$$

which yields 95% confidence limits of 1.03 and 1.23. Since the confidence limits do not include the null value of 1, the effect of a 5-year difference in age is statistically significant. We can also see that the CI obtained here (i.e., 1.03–1.23) is much narrower than that obtained for the MOSNET variable (i.e., 0.115–16.89), indicating greater precision in the estimation of the OR for the effect of AGE than obtained for the effect of MOSNET.

If, instead of a 5-year difference in age, we consider the effect of a 10-year difference in age, the formulas for the estimated adjusted OR and 95% CI become

$$\hat{OR}_{(AGE1-AGE0=10 \mid \text{mosnet, sector})} = \exp[10\hat{\beta}_1]\quad (35)$$

and

$$\begin{aligned}95\% \text{ CI for } \hat{OR}_{(AGE1-AGE0=10 \mid \text{mosnet, sector})} \\ &= \exp[10\hat{\beta}_1 \pm 1.96(10s_{\hat{\beta}_1})]\end{aligned}\quad (36)$$

respectively. The corresponding computed values are 1.28 for the adjusted OR and 1.07 and 1.52 for the confidence limits.

Thus far, we have only considered models with main effect variables like MOSNET, AGE, and SECTOR; we have not considered product terms such as $\text{MOSNET} \times \text{AGE}$. When the model contains product terms (that include the exposure variable), the simple equation (14) for obtaining the adjusted OR does not work. In such situations, we must use the general formula given by equation (13). Let us consider the model given below, which, in addition to the terms contained in the model shown in equation (21), contains the product term $\text{MOSNET} \times \text{AGE}$:

$$\begin{aligned}\text{logit}[\Pr(Y = 1)] \\ &= \beta_0 + \beta_1(\text{AGE}) + \beta_2(\text{MOSNET}) \\ &\quad + \beta_3(\text{SECTOR1}) + \beta_4(\text{SECTOR2}) \\ &\quad + \beta_5(\text{SECTOR3}) + \beta_6(\text{SECTOR4}) \\ &\quad + \beta_7(\text{MOSNET} \times \text{AGE})\end{aligned}\quad (37)$$

Table 2 Maximum likelihood estimates obtained by fitting the logistic model shown in equation (37) using the LOGISTIC procedure in SAS

Parameter	Estimate	Standard error	Wald > χ^2	Pr > χ^2	Odds ratio
Intercept	−0.8080	1.6311	0.2454	0.6203	0.446
AGE	−0.00434	0.0362	0.0143	0.9048	0.996
MOSNET	−0.8043	1.6433	0.2396	0.6245	0.447
SECTOR1	−2.2929	1.0804	4.5042	0.0338	0.101
SECTOR2	−0.6813	0.5541	1.5118	0.2189	0.506
SECTOR3	0.8153	0.4756	2.9388	0.0865	2.260
SECTOR4	0.5115	0.4515	1.2830	0.2573	1.668
MOSNET × AGE	0.0306	0.0374	0.6689	0.4134	1.031

To obtain an adjusted *OR* for the effect of MOSNET adjusted for AGE and SECTOR, we need to specify the two groups being compared – say $\mathbf{X}_A$ and $\mathbf{X}_B$, as in equation (13). For these two groups we need to specify the values of the predictor variables defined by

$$\begin{aligned} \mathbf{X} = & (\text{AGE}, \text{MOSNET}, \text{SECTOR1}, \text{SECTOR2}, \\ & \text{SECTOR3}, \text{SECTOR4}, \text{MOSNET} \times \text{AGE}) \end{aligned} \quad (38)$$

Then, to compute the *OR* between those who did not use mosquito netting relative to those who did, we need to define the two groups as follows:

$$\mathbf{X}_A = (\text{AGE}, 1, \text{SECTOR1}, \text{SECTOR2}, \text{SECTOR3}, \text{SECTOR4}, 1 \times \text{AGE}) \quad (39)$$

$$\mathbf{X}_B = (\text{AGE}, 0, \text{SECTOR1}, \text{SECTOR2}, \text{SECTOR3}, \text{SECTOR4}, 0 \times \text{AGE}) \quad (40)$$

Substituting $\mathbf{X}_A$ and $\mathbf{X}_B$ into the formula shown in equation (13) for the *OR*, we obtain

$$\begin{aligned} OR_{(\text{MOSNET}=1 \text{ vs } \text{MOSNET}=0 | \text{age, sector})} &= \exp[(\text{age} - \text{age})\beta_1 + (1 - 0)\beta_2 + (\text{sector1} \\ &\quad - \text{sector1})\beta_3 + \dots + (\text{sector4} - \text{sector4})\beta_6 \\ &\quad + (\text{age} - 0)\beta_7] = \exp[\beta_2 + \beta_7(\text{age})] \end{aligned} \quad (41)$$

Thus, rather than involving only β_2 , the preceding expression in equation (41) involves the two coefficients β_2 and β_7 , each of which is a coefficient of a variable in the model that contains the exposure variable, MOSNET, in some form. The coefficient β_7 is included because it is the coefficient of the “interaction term” in the model of equation (37). This model

essentially says that the value of the *OR* for the effect of MOSNET should vary depending on the values of the variable AGE and of the coefficient β_7 . The variable AGE in equation (37) is an example of an *effect modifier* (see **Effect Modification and Interaction**), since the effect of the exposure variable MOSNET, as quantified by the *OR* formula in equation (41) above, changes (i.e., is *modified*) depending on the value of age.

We fit the “interaction model” of equation (37) to the DENGUE dataset using the LOGISTIC procedure in SAS. Selected *ML* estimates from the output are presented in Table 2.

Previously, in equation (24), we considered the estimated *OR* for MOSNET using the “no-interaction model” shown in equation (21), but now we are using the logistic model in equation (37) instead. The estimated *OR* for the interaction model can be calculated using equation (41) as follows:

$$\begin{aligned} \hat{OR}_{(\text{MOSNET}=1 \text{ vs } \text{MOSNET}=0 | \text{age, sector})} &= \exp[\hat{\beta}_2 + \hat{\beta}_7(\text{age})] \\ &= \exp[-0.8043 + 0.0306(\text{age})] \end{aligned} \quad (42)$$

where $\hat{\beta}_2 = -0.8043$ is the estimated coefficient of the MOSNET variable and $\hat{\beta}_7 = 0.0306$ is the estimated coefficient of the (MOSNET × AGE) variable (see Table 2). The adjusted *OR* formula in equation (42) says that the value of the ratio depends on the value we specify for AGE, which is exactly what we mean when we assume (using the model in equation (37)) that age is an effect modifier of the relationship between mosquito net use and risk of contracting dengue fever.

Table 3 shows the computed values for this adjusted *OR* for various specifications of the effect modifier, age.

Table 3 Effect of age on the value of the estimated adjusted odds ratio obtained by fitting the logistic model shown in equation (37)

Age	Adjusted OR
10	0.61
15	0.71
20	0.83
25	0.96
26.28	1.00
30	1.12
35	1.31
40	1.52
45	1.77
50	2.07
55	2.41
60	2.81

Table 3 indicates that, on the basis of the interaction model in equation (37), the adjusted *OR* for the effect of mosquito net usage status varies from values below the null value of 1 when age is 25 or less to values increasingly above 1 (though below 3) when age is over 30. These results suggest, for example, that a person of age 20 who does not use a mosquito net (i.e., MOSNET = 1) is 0.83 times as likely to get dengue fever as a person who uses a mosquito net; in contrast, at age 40, a person who does not use a mosquito net is 1.52 times as likely to get dengue fever as a person who uses a mosquito net. However, this result is not statistically significant (data not shown) and we have not yet evaluated whether the model with the interaction term (MOSNET $\times$ AGE) is a better fit to the data compared to the no-interaction model.

We can obtain *CI*s for any of the adjusted *OR*s presented in Table 3 by using the general formula given below:

$$\exp[\hat{L} \pm 1.96(S_{\hat{L}})] \quad (43)$$

where $\hat{L} = \hat{\beta}_2 + \hat{\beta}_7$ (age) and $S_{\hat{L}} = \sqrt{\hat{\text{Var}}(\hat{L})}$, and where $\hat{\text{Var}}(\hat{L})$ is computed using the formula for the variance of a linear combination of random variables, which for this example turns out to be

$$\begin{aligned} \hat{\text{Var}}(\hat{L}) &= \hat{\text{Var}}(\hat{\beta}_2) + (\text{age})^2 \hat{\text{Var}}(\hat{\beta}_7) \\ &\quad + 2(\text{age}) \hat{\text{Cov}}(\hat{\beta}_2, \hat{\beta}_7) \end{aligned} \quad (44)$$

The numerical values of the variances and the covariances involving the estimated parameter coefficients are typically printed out as an option by the computer program used. For the model in equation (37), the estimated variances and covariances in the preceding variance formula are

$$\hat{\text{Var}}(\hat{\beta}_2) = 2.7004 \quad (45)$$

$$\hat{\text{Var}}(\hat{\beta}_7) = 0.001399 \quad (46)$$

and

$$\hat{\text{Cov}}(\hat{\beta}_2, \hat{\beta}_7) = -0.0435 \quad (47)$$

If, for example, we let age = 40, then

$$\hat{L} = -0.8043 + 0.0306(40) = 0.4197 \quad (48)$$

$$\begin{aligned} \hat{\text{Var}}(\hat{L}) &= 2.7004 + (40)^2(0.001399) \\ &\quad + 2(40)(-0.0435) = 1.4588 \end{aligned} \quad (49)$$

and

$$S_{\hat{L}} = \sqrt{\hat{\text{Var}}(\hat{L})} = 1.2078 \quad (50)$$

The 95% *CI* for the adjusted *OR*, using equation (43), is then given by

$$\begin{aligned} &\exp[\hat{L} \pm 1.96(S_{\hat{L}})] \\ &= \exp[0.4197 \pm (1.96)(1.2078)] \end{aligned} \quad (51)$$

which yields lower and upper confidence limits of 0.14 and 16.23, respectively. This *CI* is very wide, which implies that the point estimate 1.52 when age is 40 (see Table 3), is unreliable. Furthermore, since the *CI* includes the null value of one, a test of significance for the adjusted *OR* is not significant at $\alpha = 0.05$.

Finally, we may wish to evaluate whether the interaction model (equation (37)) forms a better fit to the data as compared to the no-interaction model (equation (21)). We can do this by using the *LR* test of the null hypothesis:

$$H_0 : \beta_7 = 0 \quad (52)$$

The full model is the model in equation (37) and the reduced model, which does not have the interaction term, is the one shown in equation (21). The following *LR* statistic was calculated:

$$\begin{aligned} \text{LR statistic} &= (-2 \log_e L_R) - (-2 \log_e L_F) \\ &= 203.706 - 202.9950.711 \end{aligned} \quad (53)$$

The statistic is approximately χ^2 with 1 *df*. The value 0.711 for the *LR* statistic is nonsignificant indicating that the no-interaction model in equation (21) is preferable to the interaction model in equation (37). In other words, the *OR* for the effect of MOSNET adjusted for age and sector is best expressed by the single value of 1.396 shown in equation (24) based on the fit of the model in equation (21), rather than by the expression in equation (42), which is based on the model in equation (37).

Conclusion

In this chapter, we have provided a brief overview of the logistic regression analysis procedure, with emphasis on describing how to obtain point estimates and *CI*s and how to conduct tests of hypothesis for *OR* parameters of interest derived from estimated regression coefficients in the model.

More detailed discussion on logistic regression, including theoretical considerations, can be found in several textbooks [1, 3–6].

In particular, these references distinguish between two types of *ML* procedures, called *unconditional* and *conditional*. The latter (conditional) procedure is typically used for logistic models in which the number of model parameters is large relative to the number of subjects being studied, as when the study design involves individual matching.

Also, Kleinbaum and Klein [5] provide a detailed discussion of the computer code to be used for logistic regression analysis in the statistical packages SAS, STATA, and SPSS [5].

Finally, in this article, we have not discussed strategies for selecting the variables that should go

into a logistic model. The goal of such a general analysis strategy is to obtain a valid estimate (in the context of epidemiologic validity and not statistical validity) of the relationship between a specified exposure and a particular disease variable, while controlling for other covariates that, if not correctly taken into account, can lead to an incorrect assessment of the strength of the exposure–disease relationship. Readers interested in this important aspect of analysis are referred to Kleinbaum and Klein [5, Chapters 6 and 7] and Kleinbaum *et al.* [6, Chapters 21–24] for a discussion of the aforementioned general analysis strategy [5, 6].

CHIRANJEEV DASH AND DAVID G. KLEINBAUM

Longevity Risk and Life Annuities

Introduction: What Is Longevity Risk?

According to the Merriam–Webster dictionary, the definition of the word *longevity* is “a long duration or length of individual life” and the word *risk*, in the broadest sense of the term, is defined as “something that creates or suggests a hazard”. Merging these two definitions implies that a long duration for individual life creates a hazard, which might seem odd to anyone not trained in actuarial science or insurance. After all, some might wonder, how can a long life be hazardous?

Indeed, although most readers would agree that a long life should be a blessing, it can be a costly one. From a personal perspective, financing 90, 95, or even 100 years of life can be expensive, especially if it is *unexpected*. This is at the heart of longevity risk. If one thinks in terms of a personal financial balance sheet, longevity risk is related to the liability side of a long life. It is the exact opposite of mortality risk, which relates to the economic cost to survivors and family because of an unexpectedly short life.

From a financial point of view, the practical implications of longevity risk come from its uncertainty as opposed to its length. If everyone knew exactly how long they would live – even if this was a very long time – longevity risk would be nonexistent and, the author’s claim is that there would then be very little interest in, and need for, a market for life annuities or general mortality-contingent claims. The greater the uncertainty around the length of human life, both individually and in aggregate, the greater is the need for a well-developed annuity market. This relatively trivial statement – that the variance is more important than the mean – has critical implications for the future of the insurance industry as it relates to the provision of retirement income, and this aspect is also discussed in this article.

On a more formal level, if the symbol $T_x^z(i) > 0$ denotes the remaining lifetime random variable for individual i , aged x in the year z (for example, $x = 65$ in the year $z = 2006$), then obviously $E[T_0^z]$ denotes general life expectancy at birth in year z . Of critical importance to the topic of longevity risk is the strong disagreement among demographers as to whether

there is a biological upper bound on $E[T_0^z]$ as z goes to 2010, 2020, and beyond.

Well-cited researchers such as Olshansky and Carnes [1] claim that life expectancy at birth is not likely to ever exceed the age of 85 or 90. These rather pessimistic authors are among a group of scholars who believe that the remarkable reductions in mortality rates across all ages during the last two centuries are a “disconnected sequence of unrepeatable revolutions” and that biological barriers create a fixed upper bound on life expectancy.

Others, such as Oeppen and Vaupel [2] take a diametrically opposing view and argue that there are no biological limits to life expectancy. They offer as evidence the fact that female life expectancy in record-holding countries has been increasing at a steady pace of 3 months per year for the last 160 years. Indeed, when (record) life expectancy in any given year is regressed against the last 160 years of data, the trend is remarkably linear with an R^2 value of 99% according to Oeppen and Vaupel [2]. These authors are extremely optimistic that biomedical research will yield unprecedented increases in survival rates.

It is precisely this disagreement among experts and the variance of professional opinion that leads to the richness and fertility of longevity risk as a research field. Likewise, in the language of financial economics, there should be a market price for the undiversifiable portion of longevity risk. This aspect is discussed in a later section.

The focus, in this article, is on three distinct aspects or dimensions of longevity risk. The first dimension deals with relation of longevity risks to individuals and their personal financial decisions. It addresses the question, How should individuals manage longevity risk? The second dimension of this article relates to the role of intermediaries and insurance companies that take on and absorb longevity risk. How can they measure and then manage this risk effectively? Is this risk priced by the market? Can it truly be diversified? The final dimension relates to the role of governments and society, as a whole, in managing longevity risk. If the private sector cannot, for whatever reason, develop a fully functional market for longevity risk, does the government have a role to play? How, if at all, should the market for (unwanted) mortality-contingent claims be regulated?

Owing to a limitation in space, the academic citations and literary references have been kept brief;

however, some key papers in all three – individual, business, and government – dimensions have been highlighted.

The interested reader is referred to [3] for a much more extensive list of relevant technical references related to the market for life annuities. In addition, the December 2006 issue of the *Journal of Risk and Insurance* is devoted entirely to the topic of longevity risk management and the interested reader is encouraged to consult these as well.

Individual Dimension: Why Buy Life Annuities?

One of the stylized facts in the research field of longevity risk and life annuities is the widespread reluctance of individuals to voluntarily purchase life annuities. Recall that life annuities can serve as a hedge against longevity risk. Modigliani [4], in his Nobel Prize lecture referred to this phenomena as the *annuity puzzle* and many papers have since been published. Indeed, in the United States less than 5% of the population of retirees has voluntarily purchased a life annuity, according to a survey conducted by the consulting firm LIMRA International. The survey of consumer finances (SCF) conducted by the Federal Reserve arrives at similar conclusions. However, inclusion of defined benefit (DB) pension income, which is also a type of annuity, increases the number of annuitized individuals. In the United Kingdom, recent changes to pension law weakened the mandatory conversion of certain tax-sheltered savings plans to life annuities at the age of 75, mostly because of public dislike and distrust of annuitization.

To understand why (immediate) life annuities remain unpopular – and the implications of this to the management of personal longevity risk – we must start at the microeconomic foundations of the demand for life annuities.

A simple two-period microeconomic example that illustrates the gains in personal utility from having access to a life annuity market is dealt with, next. Assume that an individual has an initial sum of \$1 which must be allocated and consumed during either of the next two periods. The consumption that must be selected, denoted by C_1 and C_2 , takes place for convenience at the end of the period. There is a p_1 probability that the individual will survive to (consume at) the end of the first period, and a p_2

probability of surviving to (consuming at) the end of the second period. The periodic interest rate – which is also the return on investment in this simple model – is denoted by R .

There is some disagreement as to whether individuals are able to formulate accurate and consistent probability estimates for their own survival rates (p_1, p_2). For example, Smith *et al.* [5] claim that, in general, an individual's estimates are consistent with objective mortality tables (*see Estimation of Mortality Rates from Insurance Data*), and this view is echoed by Hurd and McGarry [6] as well. In contrast, Bhattacharya *et al.* [7] claim that individuals have systematic biases in the way they perceive their own mortality rates. This is clearly an ongoing area of research.

Either way, we assume that the values of the p 's are known, and the objective is to maximize discounted utility of consumption. To make things even easier, we assume logarithmic preferences for consumption utility. This is all standard. In the absence of life annuities or any market for life contingent claims, our objective function and budget constraint would be described by

$$\begin{aligned} \max_{\{C_1, C_2\}} \text{Utility} &= \frac{p_1}{1 + \rho} \ln[C_1] \\ &+ \frac{p_2}{(1 + \rho)^2} \ln[C_2] \end{aligned} \quad (1)$$

$$\text{subject to } 1 = \frac{C_1}{1 + R} + \frac{C_2}{(1 + R)^2} \quad (2)$$

where ρ is our subjective discount rate. This “toy model” is a subset of a classical life cycle model of investment and consumptions that is at the heart of microeconomics and is described in greater length in most economics textbooks. Solving the problem, we obtain the following optimal values for consumption over the two periods:

$$\begin{aligned} C_1^* &= \frac{p_1(\rho R + R + \rho + 1)}{p_2 + p_1\rho + p_1}, \\ C_2^* &= \frac{p_2(1 + 2R + R^2)}{p_2 + p_1\rho + p_1} \end{aligned} \quad (3)$$

The ratio of optimal consumption between period one and period two is $C_1^*/C_2^* = p_1(1 + \rho)/p_2(1 + R)$. Now we arrive at the important qualitative implication.

When the subjective discount rate is equal to the interest rate ($\rho = R$), then $C_1^*/C_2^* = p_1/p_2$, which is the ratio of the survival probabilities, which is strictly greater than one. Stated differently, the optimizer will consume less at higher ages. In fact, one might rationally starve to death! This insight regarding optimal consumption over the life cycle is quite robust and explained in [4], amongst other references that extend this from two periods to continuous time. If one cannot insure or hedge one's longevity risk, which is the probability of living for two periods (as opposed to just one), then one will adapt to this risk by taking one's chances and consuming less as one ages (*see Fair Value of Insurance Liabilities*). There are alternative strategies that provide greater utility and greater consumption possibilities.

In the presence of actuarially fair life annuities – which hedge against personal longevity risk – optimal behavior is quite different. The budget constraint in equation (2) will change to reflect the probability-adjusted discount factor. The optimization problem is now as follows:

$$\begin{aligned} \max_{\{C_1, C_2\}} \quad & \text{Utility} = \frac{p_1}{1 + \rho} \ln[C_1] \\ & + \frac{p_2}{(1 + \rho)^2} \ln[C_2] \end{aligned} \quad (4)$$

$$\text{subject to} \quad 1 = \frac{p_1 C_1}{1 + R} + \frac{p_2 C_2}{(1 + R)^2} \quad (5)$$

We notice that the only difference between this and the previous optimization problem is the constraint itself. If personal longevity risk can be hedged in the insurance market, the present value of any given consumption plan will be lower. It is cheaper to finance the same standard of living if one's assets are lost at death. Annuitization involves a trade-off between utility of consumption and utility of bequest.

It is questionable whether one should use the same survival probability (p_1, p_2) in the objective function and the constraint owing to adverse selection issues in the annuity market. The interested reader is referred to the paper by Finkelstein and Poterba [8] for a discussion of this issue. Nevertheless, in this case, the optimal consumption is denoted by C_1^{**}, C_2^{**} , and is given by

$$C_1^{**} = \frac{\rho R + R + \rho + 1}{p_2 + p_1 \rho + p_1}, \quad C_2^{**} = \frac{1 + 2R + R^2}{p_2 + p_1 \rho + p_1} \quad (6)$$

The important point to notice is that $C_1^{**} = C_1^*/p_1$ and $C_2^{**} = C_2^*/p_2$, which implies that the optimal consumption is greater in both periods, when one has access to life annuities, regardless of whether adverse selection plays a significant role. Specifically, at time zero, the individual would purchase a life annuity that pays C_1^{**} at time 1 and C_2^{**} at time 2. The present value of the two life annuities – as per the budget constraint – is \$1. In this case, the ratio of consumption between period 1 and period 2 is $C_1^*/C_2^* = (1 + \rho)/(1 + R)$. When the subjective discount rate is equal to the interest rate ($\rho = R$), then $C_1^*/C_2^* = 1$.

The point in all of this algebra is as follows. *Buying a life annuity allows rational consumers to eliminate or hedge their personal longevity risk.* Of course, in the absence of life annuities, the best one can hope for is to allocate investment assets in a way that minimizes the lifetime probability of ruin (*see Ruin Theory*), which is an approach taken by Young [9], amongst others. But this is also why Yaari [10, 11], and more recently, Ameriks *et al.* [12] advocate that individuals should allocate a substantial fraction of their retirement wealth to life annuities. In fact, Yaari [10] advocates complete annuitization at any age in the absence of bequest motives. A recent paper by Milevsky and Young [13] looks at annuitization as an optimal timing problem, but all of these papers are based on the same idea. Annuitization hedges against longevity risk.

Business Dimension: Can Companies Hedge This Risk?

When individuals decide to hedge or insure their own longevity risk by transferring their personal exposure to intermediaries, these insurance companies then face aggregate mortality risk. This applies when selling life annuities or any other form of lifetime income such as guaranteed living income benefit (GLiB), which have become very popular in the US retirement market. Sometimes, longevity risk is interlinked with market and interest risk, as in the case of guaranteed annuity options (GOAs).

It is generally thought that insurance companies (or their own reinsurers) can completely eliminate mortality and longevity risk by selling enough of claims to diversify away mortality. The law of large numbers (LLN) is often invoked as a justification.

But, the truth is far more complicated. Indeed, if there is systematic uncertainty regarding aggregate mortality trends – for example, the research cited earlier by Olshansky and Carnes [1] *versus* Oeppen and Vaupel [2] – then selling more annuities and longevity-related insurance will not necessarily eliminate idiosyncratic risk. The following example should help explain the impact of the stochasticity of aggregate mortality.

Assume that an insurance company sells a one-period longevity insurance policy that pays \$2 if the buyer survives to the end of the period, but pays nothing if the buyer dies prior to this date. Assume the insurance company issues N of these policies – at a price of \$1 per policy – to N independent lives, each of whom has an identical probability p of surviving and probability $(1 - p)$ of dying prior to the payout date. Each longevity insurance policy generates an end-of-period Bernoulli liability for the insurance company. The random variable w_i can take on a value \$2 with probability p and a value of \$0 with probability $(1 - p)$. The expected value $E[w_i] = 2p$ and the variance is $\text{var}[w_i] = p(2 - 2p)^2 + (1 - p)(0 - 2p)^2 = 4p(1 - p)$. In the simple case that $p = 0.5$, this collapses to $E[w_i] = 1$ and $\text{var}[w_i] = 1$, as well as $\text{SD}[w_i] = 1$.

Let the random variable, $W_N = \sum_{i=1}^N w_i$ denote the insurance company's aggregate liability at the end of the period owing to selling a portfolio of longevity insurance policies. These independent longevity insurance exposures leave the issuing company facing an aggregate expected payout of $E[W_N] = N2p$, an aggregate variance of $\text{var}[W_N] = N4p(1 - p)$, and an aggregate standard deviation of $\text{SD}[W_N] = 2\sqrt{Np(1 - p)}$. The independent and identically distributed (i.i.d.) nature of the exposures allows me to add up the individual variances. This immediately leads us to the well-known results that the standard deviation per policy (SDP) goes to zero in the limit as $N \rightarrow \infty$. Stated technically,

$$\lim_{N \rightarrow \infty} \frac{1}{N} \text{SD}[W_N] = \lim_{N \rightarrow \infty} 2 \frac{\sqrt{p(1 - p)}}{\sqrt{N}} \rightarrow 0 \quad (7)$$

This is a special case of the LLN, which states that $\lim_{N \rightarrow \infty} \frac{1}{N} W_N \rightarrow p$. If the insurance company sells enough of these longevity insurance policies their risk exposure (per policy) goes to zero. Yet another interpretation of this statement is that longevity risk is completely diversifiable and not compensated by markets in equilibrium, when claims are i.i.d.

What happens when the probability parameter p is unknown? This is a critical aspect of longevity risk. It is an aggregate longevity risk as opposed to a personal longevity risk. This is also equivalent to not knowing the hazard rate or instantaneous force of mortality underlying the probabilities, modeled in various recent papers such as [14], or [15]. Stated differently, What if we have an estimate of p *versus* a certainty for p ?

The underlying payoff function in this simple example is now defined as $w_i^* = 2$ with probability $\tilde{p}$ and $w_i^* = 0$ with probability $(1 - \tilde{p})$. The asterisk on top of the w_i^* reminds the reader that the parameter $\tilde{p}$ itself has its own (symmetric) distribution, which it is assumed takes on a value of $p + \pi$ with probability $1/2$ and a value of $p - \pi$, with a probability of $1/2$.

Obviously a restriction must be imposed on the newly defined uncertainty parameter π , namely, that $\pi \leq 1 - p$ and $p > \pi$. Also, by definition $E[\tilde{p}] = 0.5(p + \pi) + 0.5(p - \pi) = p$. For example, one might assume that $\pi = 0.1$, $p = 0.5$ so that $\tilde{p}$ takes on values of either 0.6 or 0.4. The intuitive interpretation for this would be that while the expected value $E[\tilde{p}] = 0.5$ of the survival probability is 0.5, it is equally likely to take on a value of 0.4 (an improvement in mortality) or 0.6 (a worsening mortality).

Now define the total (aggregate) exposure of the insurance company by the notation $w_N^* = \sum_{i=1}^N w_i^*$, with the immediate implication that $E[W_N^*] = N2p$, which is identical to the traditional (deterministic) case. The key difference between W_N (deterministic mortality) and W_N^* (stochastic mortality) lies in the term for the variance. We are no longer entitled to add up the individual variance terms owing to the implicit dependence created by the common $\tilde{p}$ factor. In this case – and one might argue, in reality – they are not i.i.d. claims. The interested reader is referred to [16] for an extensive discussion on this point, in which it is also shown that

$$\text{var}[W_N^*] = 4Np(1 - p) + 4N\pi^2(N - 1) \quad (8)$$

This collapses to the familiar and intuitive $4Np(1 - p)$ when $\pi = 0$, and we are back to the deterministic mortality world. Note also that when $N = 1$, the variance of the payout is the same $4Np(1 - p)$ it would be under the deterministic case, which means that an individual policy is not any riskier under a stochastic $\tilde{p}$ *versus* a deterministic $p = E[\tilde{p}]$. It is the portfolio aggregation that creates the extra risk.

For example, if an insurance company sells $N = 10\,000$ longevity insurance (also known as *term life annuity*) policies under the parameter set $\pi = 0.1$, so that $\bar{p}$ takes on a value of either 0.6 or 0.4 with equal probability, the variance of the aggregate payout to the insurance company becomes $0.96N + 0.04N^2$ according to equation (8). Notice the N^2 term. The variance grows nonlinearly in N , which means that the SDP $\sqrt{0.96N + 0.04N^2}/N$, will converge to a constant 0.2 instead of zero when $N \rightarrow \infty$. No matter how many longevity insurance policies the company issues, the uncertainty (risk) per policy will never be less than \$0.20 per \$1.00 of expected payoff. The risk never goes away. Diversification can only reduce risk up to a certain point. In general, we have that $\lim_{N \rightarrow \infty} \frac{1}{N}SD[W_N^*] \rightarrow 2\pi$. The SDP converges to the total spread (2π) in the probability (hazard) rate.

What does all of this mean to companies who are trying to manage their own longevity risk? The main take-away is as follows. There is a growing body of research that attempts to model the evolution of aggregate morality, for example the trend in $E[\mathbf{T}_0^z]$, for $z = 2006, 2007, 2008$, etc. Various stochastic processes have been proposed and calibrated, starting with work by Lee and Carter [17], Olivieri [18], Dahl [19], Renshaw and Haberman [20], Carnes, Blake and Dowd [21], as well as Biffis and Millossovich [22]. This is also related to the pricing of GOAs, which is addressed in [23]. All of these papers are effectively based on the same underlying argument. One does not know with certainty the evolution of the dynamics of $\mathbf{T}_x^z$ or even $E[\mathbf{T}_x^z]$.

Government Dimension: Should They Get Involved?

Finally, if longevity risk is faced by individuals and corporations, this becomes a public policy issue as well. If individuals do not value the longevity insurance benefits provided by life annuities and are perhaps myopic in their investment behavior, should government mandate annuitization for tax-sheltered savings plans and other forms of personal pensions? Should governments actively try to correct behavioral biases by subsidizing (entering) the annuity market and making it more appealing to individuals? What can government policy do to encourage a deeper market for annuities? Along these lines, some

researchers have advocated that government issue longevity or survivor bonds as a way for governments to help insurance intermediaries, as well as pension funds cope with longevity risk that cannot be diversified away using the LLN. See, for example, [24], for this line of thinking. Other policy-oriented papers include [25], which examines the role of life annuities in a privatized social security system, or [26], which examines the role of annuities within pension plans, appear to favor the involvement of the private sector to find solutions to this problem. A number of these issues are addressed in the December 2006 issue of the *Journal of Risk and Insurance*, and do not require further elaboration.

To sum up, longevity risk – regardless of how it is defined – is faced by individuals, corporations, as well as society and their governments. In a brief article such as this, it is virtually impossible to review or discuss all papers within this broad field. This article has given a brief overview of the various dimensions and aspects of longevity risk as they relate to the market for life annuities and mortality-contingent claims. It is believed that this field will continue to provide fertile ground for advanced research for many, albeit uncertain, years to come (*see Life Insurance Markets; Equity-Linked Life Insurance; Fair Value of Insurance Liabilities; Pricing of Life Insurance Liabilities; Asset-Liability Management for Life Insurers*).

Low-Dose Extrapolation

Extrapolation, in its most basic statistical sense, is the construction of inferences about a stochastic phenomenon based on data unassociated or only partially associated with the phenomenon. As Hertzberg [1] aptly puts it, the process involves making “inferences about data-poor scenarios . . . from studies of data-rich scenarios”. A variety of applications in quantitative risk assessment involve some form of extrapolation. A well-known, and perhaps infamous, example occurs in health risk assessment, where a major goal is estimation of the severity and likelihood of damage from hazardous stimuli to humans [2]. To identify the damaging effects of a hazardous agent, investigators often perform bioassays on small mammals (*see Dose-Response Analysis*). When the experiment is conducted as a screen for certain toxic effects [3, 4], there is typically a relatively short time span available for the animals to exhibit the toxicity. Thus the design of the assay will require the data be taken at fairly high-dose levels. In these cases, decisions on occupational or environmental exposure standards to the toxic agent must be extrapolated from the high-dose exposure data. Similar issues can occur in select human observational studies of toxic exposures [2, 5].

These types of *low-dose extrapolations* can result in suspect inferences, however, if the lack of observed low-dose information is substantial [6–8]; indeed, considerable research attention has been directed at improving low-dose extrapolations in risk analysis [9–11]. A common assumption is that the model structure is essentially unchanged at low-dose levels. Unfortunately, numerous gaps remain in methodological understanding and implementation of low-dose extrapolations when used to support quantitative risk assessments, owing in part to excess variation and uncertainty in low-dose risk estimates from laboratory or human population studies; see, e.g., [12] or [13], respectively. Because of these gaps, the general problem of low-dose risk extrapolation remains an open issue from both a statistical and a public health policy perspective.

A particular problem connected with this occurs when estimation centers on dose(s) related to a particular, small health effect level. If the health effect/risk is small enough to be regarded as nonadverse or “acceptable”, it is likely to be far below the observed

range of the response data. As a result, the terminology can seem misleading: estimation and inferences are conducted on the dose scale, but the extrapolation is actually conducted from “high” observable effects/levels of risk to much lower effects/levels of risk. (Perhaps the term *low-effect extrapolation* would be more adequate!)

Recent advances in quantitative risk-benchmark analysis [14] (*see Benchmark Analysis*) and estimation of benchmark doses (BMDs) [15–17] have addressed some of these issues, although further developments are needed. Model selection and model quality assessment are particularly important in this respect: it is well recognized that many models can produce reasonably stable point estimates at higher doses, but can break down or diverge greatly at low doses corresponding to very low response rates [18, 19]. As a result, many laboratory studies limit estimation to (benchmark) risk levels in the 1–10% range, and not much lower [20]. When the data relate to a serious health effect such as cancer or developmental damage, this level of risk/response is usually very high. For example, regulations pertinent to carcinogen exposures are often considered at risks at or below 10^{-3} (i.e., one in a thousand) or 10^{-4} (i.e., one in ten thousand); but, toxicology data are often quantal, and as such they rarely produce observed rates of response below 1/50 or 1/100. (This is of less concern when data are taken on a continuous scale [21] and the benchmark effect is based on a percent change in response, e.g., a 5% change in body weight. In these cases, the benchmark is often much more likely to actually have been observed in the data, and as such no “low-dose” extrapolation is required.)

Developments in biological models or other forms of mechanistic modeling for adverse-outcome data may lead to improvements in such low-dose/low-effect extrapolations. This may be an area of future advancement [1, 22, 23], if current limitations in the application of such models can be overcome [10, 24]; this includes issues with the assumption of thresholds [25, 26] and/or approximate low-dose linearity in the dose–response [27, 28]. Connected with this, the increasing use of model averaging [29] and other ways of incorporating model uncertainty [30] may also prove advantageous.

It is also worth emphasizing that the issue of extrapolation in quantitative risk assessment includes and is extended to challenges well past that of

low-dose/low-effect estimation. Issues of inter and intraspecies extrapolation come quickly to mind [31, 32], along with potency estimation [33, 34] and extrapolations necessary in ecological risk assessment [35]. Hertzberg [1], mentioned earlier, gives a useful review of the larger issue; also see Preston [36].

Acknowledgments

Thanks are due Dr. Wout Slob for his helpful suggestions on this topic. Maintenance Modeling and Management

Maintenance management and modeling is, essentially, concerned with describing a system in terms of its constituent parts and associating maintenance actions or rules with these parts. This view was first formalized by Gits [1]. When resolving a system into its constituent parts, it is helpful to use the following definitions of Ascher and Feingold [2]: a *component* is defined as an element of a maintained system for which it is reasonable to investigate a bespoke maintenance action. A *socket* is defined as the interface of a component with the maintained system; together with the component it provides a defined operational function within the system for which failure can be defined in terms of its impact on the system performance. The *system* is the totality of its parts: sockets, components, and their interrelationships that together provide some product or service. A system may be represented as a connected set of sockets into which components are installed. Within this framework, it is the role of maintenance management and modeling to resolve a system into its constituent sockets and components, to assign maintenance actions appropriate to each component, and to combine these actions into maintenance schedules or rules in an optimal manner. The resolution of the system and corresponding set of maintenance rules is the maintenance design.

It is important to recognize that maintenance management of a system may differ depending on one's viewpoint. Thus, a maintenance design is not unique. An organization that uses the operational function of a system may propose a different maintenance design to an organization that supplies the operational function. Differing organizational drivers and resources will imply differing maintenance designs, although the techniques described in this article are applicable regardless of viewpoint and whether maintenance or even the provision of operational function is outsourced. For example, an organization that provides urban, underground transportation may – (a) own and maintain its station escalators, or (b) own its escalators but outsource their maintenance to the original equipment manufacturer (OEM) or a third party, or (c) outsource escalator function to the OEM or a third party. Thus, with respect to (c), the transport

organization is not concerned at all with escalator equipment but merely has functional requirements that it demands (for payment) from the supplier. In each of the three cases, a maintenance design is necessary, but the owners of the maintenance design will differ. In (a), the owner is the user, in (c) it is the supplier, and in (b) we would expect the user and supplier to share ownership. While the techniques used to develop the design should not differ, the objectives that are used to define the system and set maintenance rules may differ.

Appropriate maintenance actions will be a matter of engineering judgment regarding the system of interest. Generally, the following three levels of maintenance intervention can be distinguished: inspection, service (for example, routine adjustment, cleaning), and replacement. Here, by replacement we mean component replacement; where maintenance interventions and replacements are combined into a program of maintenance to be carried out on the system at a particular point in time, then the term *refurbishment* or *overhaul* might be used to describe the program of maintenance depending on its scale. Other actions that are maintenance driven but are not strictly maintenance activities are operator training, and redesign and retrofitting. In the former, functional degradation resulting from inappropriate use of plant may be moderated. As an example of redesign and retrofitting, the Mass Transit Rail Corporation Limited (MTRCL) of Hong Kong is concerned with escalator performance at its stations and found that the redesign and retrofitting of escalator control systems would allow a significant reduction in stoppages owing to transient power dips [3]. Although the retrofitting of new control systems at MTRCL was maintenance driven, funding for the work did not come from the maintenance budget but was part of a large capital expenditure program. Complete system replacement may also be maintenance driven, and therefore, a consideration in the maintenance design. As alluded to, the funding for such action would not normally come from a maintenance budget. However, from a maintenance modeling point of view, system replacement may be regarded as the extreme case of redesign and retrofitting, since with system replacement one would expect a significant improvement in functional capability (which may not be the case with overhaul).

The extent of the resolution of a system into its constituent parts is a key consideration in the

maintenance design. If the resolution is too fine, the collection of all maintenance tasks will be too large and complex to manage effectively. If it is too coarse, the maintenance tasks will be suboptimal. For example, a complete pump might be replaced when renewal of seals and bearings would suffice. The principles of this resolution are an interesting avenue for study. Much of the maintenance modeling that seeks “optimal” policy in relation to a particular component function typically assumes that the system has been resolved at an appropriate level. Also, appropriate definitions of operational function and failure have to be agreed upon by parties that own the maintenance design. As for the escalators, MTRCL would regard an escalator stoppage owing to a power dip as a failure of operational function. However, these events would not, typically, be recorded as escalator failures by the OEM engineers.

Maintenance design in Gits [1] is conceptual. Labib [4] proposes a practical approach. Here a large complex system is resolved into components that possess operational failure characteristics (*see Systems Reliability*), which can be summarized in terms of a small number of key measures. Two such measures are, for example, average downtime per failure (downtime) and number of failures per unit time (frequency) (*see Managing Infrastructure Reliability, Safety, and Security; Common Cause Failure Modeling*). Other alternative measures may be used or the approach can be extended to higher dimensions. Following a standard Pareto analysis (*see Supra Decision Maker*), components are then classified by these measures and plotted on a multidimensional Pareto chart. Such a chart is conceptualized in Figure 1, and classes of maintenance actions that would be appropriate in general are superimposed on this chart. The interpretation of these maintenance actions is as follows. A system which is experiencing frequent, minor stoppages (top left) is likely to be investigated within a program of continuous engineering improvement. This may be considered as a quality management issue, and operator training is frequently a key response. Components incurring frequent, high downtime failures typically require urgent redesign, as such failures have significant impact on system performance. For example, Amasaka and Osaki [5] describe the redesign of an oil seal component in an engine following frequent warranty claims. Low frequency and low downtime components are allowed to operate to failure. Low

Figure 1 Schematic classification diagram of appropriate maintenance actions based on two decision criteria – average downtime per failure and frequency of failure, with indicative maintenance actions

frequency and high downtime events are likely to be seen by engineers as a prediction problem; condition-based maintenance is expected to focus on such events and the underlying components. A component for which the required maintenance policy is less clear is the subject of traditional ongoing maintenance schedules (use-based maintenance). An example of such a chart is shown in Figure 2 for the principal components of an extrusion press that has been used in the manufacture of copper products for a number of years. It is noticed that no components lie in the maintenance driven redesign region, which is expected – given the maturity of the system here.

With improvements achieved over time, the classification is updated with units previously classified as use-based maintenance becoming the focus of condition-based maintenance, say. In this way, the notion of continuous improvement in the performance of the system can be visualized. Also, higher dimensional Pareto charts may be used when other failure characteristics, such as the cost of lost production, are considered.

One might generalize the above approach within a risk assessment framework. The frequency of failure may be interpreted as a probability, p , and the downtime as the consequences, C (the consequences might equivalently be measured in other terms such as cost or some safety-related measure). With risk defined

Figure 3 Risk-based maintenance – schematic classification diagram of appropriate maintenance actions based on risk, with lines of equal risk indicated

by $R = p \times C$, Figure 1 may then be redrawn as shown in Figure 3 with lines of equal risk indicated. Low risk components are thus subject to failure-based

maintenance. High risk components are subject to redesign and retrofiting. Components that are in the medium risk region and not subject to improvement through operator training should then be the focus of either use- (or time-) based maintenance or condition-based maintenance (see **Reliability Growth Testing**), and many models have been developed to aid decision making in these contexts.

The simplest of the use-based models are those concerned with component replacement, notably block replacement and age-based replacement. In age-based replacement, the age of a component is monitored and replacement is initiated when the age reaches some critical level, T . This critical level may be naturally expressed in terms of the hazard function [7]. To choose this critical level optimally, information about the time to failure distribution of the component is required; the optimality criterion must also be specified, for example, as the long-run cost per unit time or the mean time between component failures. When component age is not monitored, then replacements may be scheduled periodically as with block replacement [8], or modified block replacement [9], or according to the constraints of maintenance budget. For an extensive discussion of optimality criteria in age-based replacement, see [10]. Component replacement times may also be determined using the techniques of reliability-centered maintenance [11].

A natural extension of age-based replacement is the modeling of the hazard of failure as a function of age and a condition indicator. Proportional hazards modeling (see **Lifetime Models and Risk Assessment; Hazard and Hazard Ratio; Statistical Arbitrage**) is an established method of looking at this problem, and the critical region for replacement can be specified in a relatively straightforward manner [12, 13]. The proportional hazards model assumes

$$h\{t, x(t)\} = h_0(t) \exp \{\beta x(t)\} \quad (1)$$

where $h_0(t)$ is the baseline hazard rate depending on system age only and $\exp\{\beta x(t)\}$ is a multiplicative risk factor that models the effect of system characteristics, with $x(t)$ being a vector of time-dependent covariates (the condition indicator), and β a vector of parameters. If the baseline hazard is unspecified, then equation (1) is the semiparametric proportional hazards model (PHM) [14]. A fully parametric proportional hazards model can be obtained by specifying $h_0(t)$ with Weibull hazard, for example: $h_0(t) = \alpha(t/\eta)^{\beta-1}/\eta$. Given a sample

of lifetime histories, ending in failure or preventive replacement (censored failure time), parameters of this model can be estimated. Given failure and preventive replacement costs and an increasing hazard, an optimal control limit for replacement, d^* , for the hazard (and hence the critical region for replacement) can be determined. Finally, for this model to be useful for the prediction of time to replacement, a model for the development of the condition indicator, $x(t)$, is required such as a discrete Markov process, $\Pr\{X(t+1) \leq x | X(1), \dots, X(t)\} = G\{x | t, X(t)\}$ [12], or a gamma process [15]. This model will then allow the prediction of future condition, $X(t+k)$ given condition history $X(1), \dots, X(t)$.

The approach may be considered natural because optimum policy would reduce to that of age-based replacement when true condition appears unrelated to the condition indicator on the basis of available data. Furthermore, the aging of the system can be accommodated by including a subset of covariates which reflect system age, e.g., number of previous repairs/replacements since new. The key problem, however, is having sufficient data on failures and covariates to estimate model parameters and hence adequately estimate the critical region.

When a failure threshold, c (see **Simulation in Risk Management; Extreme Values in Reliability**), for the component condition, Y , is specified (so that if $Y > c$ then the component fails), an alternative modeling approach may be used. For simple cases, Y may be directly observable (e.g., tyre tread depth), and it is sufficient to model this wear process using a suitable stochastic process, such as the gamma process [16]. This has been referred to as a direct monitoring process [17]. At a particular decision point, given the development of the condition to date, y_{t-} (condition history), the problem is to estimate the residual life or remaining time to failure, that is, the minimum time T , such that $Y_T > c | y_{t-}$. An estimate of the residual life distribution (see **Pricing of Life Insurance Liabilities; Reliability Growth Testing**), $f(T | y_{t-})$ can be used to optimize the time to replacement given a suitable decision criterion. This optimal time to replacement can be updated dynamically as more condition information becomes available. In practice, the decision would be a choice between replacing before the next monitoring check (inspection) or otherwise. Where the process is measured continuously, the replacement problem is trivial involving replacement at the moment $Y = c$. The

current condition may be unobserved, but an indicator of condition, X , is typically observed and used as a surrogate. Provided the condition, Y , can be calibrated in terms of the condition indicator, then in principle the method can proceed as if the condition were directly observable. The calibration is done typically by relating the condition indicator to the condition observed at preventive replacements or on failure, with the latter expected to be rare events. This method was developed for monitoring the refractory thickness in an induction furnace [18]. It has also been used in the vibration analysis of bearings [19].

The specification of a failure threshold may not be feasible. It is necessary to specify a warning threshold to proceed. If the condition indicator is above the threshold, then the component is defective and should be replaced. If the condition indicator is monitored continuously, then the decision problem is again trivial. If the condition indicator is monitored periodically, and the condition indicator only takes the values 0 and 1 (depending on whether the measured condition is above or below the warning threshold), then we will be naturally concerned with how often to monitor. A two-phase or delay-time model [20, 21] (see **Repair, Inspection, and Replacement Models**) can be used to optimize the monitoring interval. In addition to the times between inspection, the warning level may also be regarded as a decision variable [22]. These models balance the cost of monitoring or inspection and preventive replacement against the cost of failure, given the probability distributions of the time at which the condition indicator crosses the warning threshold and the time between the condition indicator crossing of the warning threshold and the consequent failure. The former time is called the *defect initiation time*, with distribution function G , say, and the latter is called the *delay time* with distribution function F , say. Let the costs of failure, monitoring inspection, and preventive replacement at monitoring inspection be C_f , C_i , and C_r , respectively. Suppose, monitoring checks are carried out every Δ time units, and that the component is replaced if the condition indicator is above the warning threshold. Under these assumptions, the long-run cost per unit time is

$$\frac{(C_f - C_r - C_i)\{1 - S(\Delta)\} + C_r G(\Delta) + C_i}{\int_0^\Delta S(t) dt} \quad (2)$$

where $S(t) = 1 - \int_0^t g(u)F(t-u) du$. Here $S(t)$ is the survival distribution (or reliability function) (see **Options and Guarantees in Life Insurance; Risk Classification/Life; Default Correlation**) of the time to failure, and hence the convolution of g , the density of defect initiation time, and the delay-time distribution. The expression (2) can be minimized to determine the optimal value of Δ . We might use the term *warning threshold condition-based maintenance* for the resulting policy. The model can be extended to consider imperfect monitoring and systems for which the delay time is related to the initiation time [23].

Where the cost of monitoring is insignificant, then on-line continuous monitoring will be appropriate, provided the warning threshold is set to allow sufficient time to schedule replacement subsequent to the alarm. The setting of the warning threshold may require modeling. Such on-line continuous monitoring systems are common (e.g., an oil level indicator light).

Given observations on the development of the condition indicator, we may wish to predict the time to the crossing of the warning threshold. Appropriate models are then, as discussed above, with the threshold giving a subtly different interpretation. Care has to be taken with definitions because what the plant operator regards as a failure threshold may be regarded as a warning threshold by modelers, and *vice versa*.

Use-based maintenance policies can be considered as special cases of condition-based maintenance policies. For example, age-based replacement can be considered as a proportional hazards condition-based maintenance policy with an uninformative condition indicator. Routine scheduled inspection maintenance can be considered as a warning threshold policy, as could the modified block replacement with the age being the "condition indicator". Block replacement is itself a special case of modified block replacement, with replacement regardless of age.

The models described thus far assume that the component is renewed on replacement. Where components are not renewed but are merely repaired, then these models may only provide approximate solutions. This assumption is relaxed in models of imperfect maintenance [24, 25].

The cost of data collection is a significant issue in the implementation of a maintenance design. Sufficient data (relating to failures) for estimating the parameters of the component failure models is

unlikely to exist in most, if not all, practical cases. Collecting data may be an option, but few operators are prepared to let components run to failure, and often, replaced components are not in a "failed" state. Also, information most closely related to such condition is likely to be more costly to collect. Oil analysis of a gearbox sump is significantly easier than an internal inspection. Thus, it may be necessary to build the cost of data collection into decision models, and it is important to consider whether condition monitoring, for example, will be effective in reducing overall costs. The costs of data collection need to be balanced against the expected gains as a result of operating a policy, which is nearer to optimal.

Given the replacement and inspection times for the components in a system, these may be combined into schedules that take account of component dependencies. Thus, certain component groups, due to their physical proximity, may be most sensibly maintained simultaneously. Models for scheduling maintenance for multicomponent systems in an opportunistic fashion are also well developed [26]. Wang [27] reviews these models (and also many other models for single-component systems). Sophisticated maintenance policies for two-component systems with failure mechanisms that interact have been developed [28–30]. Given that many systems are large and complex (e.g., oil production platforms, nuclear power plants), there is scope for the use of expert systems in the designing and scheduling of maintenance activity. Such work is the focus of ongoing research [31].

The static policies implied by block replacement and routine preventive and inspection maintenance are relatively straightforward to schedule, even for complex systems. However, where age-based replacement or condition-based maintenance is implemented, such systems will need to schedule maintenance activities in a dynamic way [32], as the execution times of certain activities will be continually updated as components age and degrade. Opportunities for combining the execution of maintenance activities on components that are dependent will also evolve over time. These aspects of maintenance design present challenges for maintenance management information systems.

PHILIP A. SCARF

Managing Foodborne Risk

Health risks in the food supply often arouse strong political passions and polarized science-policy debates. From fear of genetically modified organisms (GMOs) and irradiated meats to rare but incurable fatal brain-wasting caused by beef contaminated with bovine spongiform encephalitis (BSE, or “mad cow” disease) to *Escherichia coli* outbreaks in retail foods to concern over antibiotic-resistant pathogens in meat, real and perceived risks associated with the food supply – and political and popular reactions to them – make headlines (*see Risk and the Media*).

What makes food safety risks so gripping? And how can methods of quantitative risk assessment (QRA) and risk management help to improve food safety? This article summarizes recent answers to these questions and surveys methods for quantifying and managing foodborne risks.

Foodborne Risks Depend on the Decisions of Many Parties

The risk of human illnesses caused by pathogenic (disease-causing) bacteria such as *Salmonella* or *E. coli* in food depends on the levels of care taken by multiple participants at steps throughout the chain of food production, distribution, and preparation. For meats, these steps can include farming (including practices for hygiene and microbial count control), transportation, slaughter, production and packaging, storage, retail, and food preparation in the kitchen – especially, proper cooking. Consumers with compromised immune systems (for example, patients with cancer, AIDS, or organ transplants) can be hundreds or thousands of times more at risk than consumers with healthy immune systems. The usual effects of foodborne illness include diarrhea and possibly fever, vomiting, and other symptoms of food poisoning. Occasionally, more serious harm, or death, may occur, depending on the pathogen and the victim.

In such a setting, where consumer risk varies greatly among individuals and depends on the actions of many different economic agents, allocating responsibility for maintaining food safety involves overlapping questions of economic efficiency, legal liability,

producer quality control, and consumer negligence or care in kitchen hygiene and in food handling and preparation. Consumers might feel that producers should guarantee a “safe” product (although eliminating all bacteria at retail may be a practical impossibility unless one relies on unpopular techniques such as irradiation); while producers may feel that consumers should exercise prudence and responsibility by cooking meat properly (which eliminates most risks from bacterial pathogens) and by maintaining good kitchen hygiene. Although government inspection and certification can help to assure reasonable microbial safety throughout much of the food chain, the question still remains of how much cost of care, responsibility, and liability should be required from each participant in the chain, given that the final risk per serving of food to a consumer depends on their joint actions.

QRA can help to improve decisions in this complex and contentious area by providing quantitative estimates of how proposed changes in the process will affect human health risks. Human health risks are typically quantified as expected number of illnesses, fatalities, illness-days, or quality-adjusted life years lost to illness per year (for population risks) or per capita-year (for individual risks). Different subpopulations, such as infants, the elderly, and people with weak immune systems (e.g., transplant, leukemia, or AIDS patients) may have distinct risks. A thorough QRA quantifies the individual and population risks for such subpopulations as well as for the whole population of concern (e.g., the whole population of a country).

Farm-to-Fork Models Quantify Microbial Loads in Food, *x*

One approach to quantifying the effects of different interventions on risks created by bacteria in food is to simulate the flow and growth, or reduction, of microbial loads of bacteria throughout the chain of steps leading from production to consumption. This is done by collecting data on the conditional frequency distribution of microbial loads leaving each step (e.g., transportation, processing, storage, etc.), given the microbial load entering that step. Microbial loads are expressed in units such as colony-forming units (CFUs) of bacteria per unit (e.g., per pound, per carcass, etc.) of food.

The discipline of applied microbiology supplies empirical growth curves and kill curves for log increase or log reduction, respectively, in microbial load from input to output of a step. These curves describe the output : input ratio (e.g., a most likely value and upper and lower statistical confidence limits) for the microbial load passing through a stage as a function of variables such as temperature, pH, and time.

A “farm-to-fork” simulation model can be constructed by concatenating many consecutive steps representing stages in the food production process. Each step receives a microbial load from its predecessor. It produces as output a microbial load value sampled from the conditional frequency distribution of the output microbial load, given the input microbial load, as specified by the microbial growth model describing that stage. Measured frequency distributions of microbial loads on animals (or other units of food) leaving the farm provide the initial input to the whole model. The key output from the model is a frequency distribution of the microbial load, x , of pathogenic bacteria in servings of food ingested by consumers.

Risk-reducing factors such as antimicrobial sprays and chilling during processing, freezing or refrigeration during storage, and cooking before serving are often modeled by corresponding reduction factors for microbial loads. (These may be represented as random variables, e.g., with lognormal distributions and geometric means and variances estimated from data.) The complete model is then represented by a product of factors that increase or decrease microbial loads, applied to the empirical frequency distribution of initial microbial loads on which the factors act. Running the complete farm-to-fork model multiple times produces a final distribution of microbial loads on servings eaten by consumers. Some farm-to-fork exposure models also consider effects of cross-contamination in the kitchen, if pathogenic bacteria are expected to be spread to other foods by poor kitchen hygiene practices (e.g., failure to wash a cutting board after use).

In summary, farm-to-fork simulation models can provide an estimate of the frequency distribution of microbial loads ingested by consumers in servings of food, as well as estimates of how these frequency distributions would change if different interventions (represented by changes in one or more of the step-specific factors increasing or decreasing microbial

load) were implemented. For example, enforcing a limit on the maximum time that ready-to-eat meats may be stored at delis or points of retail sale before being disposed of limits the opportunity for bacterial growth prior to consumption. Changing processing steps (such as scalding, chilling, antimicrobial sprays, etc.) can also reduce microbial loads. Such interventions shift the cumulative frequency distribution of microbial loads in food leftward, other things being held equal.

Dose–Response Models for Foodborne Pathogens, $r(x)$

Several parametric statistical models have been developed to describe the relation between quantity of bacteria ingested in food and the resulting probability of illness. One of the simplest is the following exponential dose–response relation:

$$r(x) = \Pr(\text{illness} \mid \text{ingest microbial load} = x \text{ CFUs}) \\ = 1 - e^{-\lambda x} \quad (1)$$

This model gives the probability that an ingested dose of x CFUs of a pathogenic bacterium will cause illness. $r(x)$ denotes this probability. The function $r(x)$ is a *dose–response curve* (see **Dose–Response Analysis**). λ is a parameter reflecting the potency of the exposure in causing illness. Sensitive subpopulations have higher values of λ than the general population.

More complex dose–response models (especially, the widely used beta-Poisson model) have two or more parameters, e.g., representing the population distribution of individual susceptibility parameter values and the conditional probability of illness given a susceptibility parameter. The standard statistical tasks of estimating model parameters, quantifying confidence intervals or joint confidence regions, and validating fitted models can be accomplished using standard statistical methods such as maximum-likelihood estimation (MLE) and resampling methods. The excellent monograph by Haas *et al.* [1] provides details and examples. It notes that “It has been possible to evaluate and compile a comprehensive database on microbial dose–response models.” Chapter 9 of this monograph provides a compendium of dose–response data and dose–response curves along with critical evaluations and results of validation studies for the following: *Campylobacter jejuni*

(based on human feeding study data), *Cryptosporidium parvum*, pathogenic *E. coli*, *E. coli* O157 : H7 (using *Shigella* species as a surrogate), *Giardia lamblia*, nontyphoid *Salmonella* (based on human feeding study data), *Salmonella typhosa*, *Shigella dysenteriae*, *Shigella flexneri*, *Vibrio cholerae*, Adenovirus 4, Coxsackie viruses, Echovirus 12, Hepatitis A virus, Poliovirus I (minor), and rotavirus. Thus, for many foodborne and waterborne pathogens of interest, dose–response models and assessments of fit are readily available.

Quantitative Risk Characterization for Microbial Risk Assessment and Risk Management

Sampling values of x from the frequency distribution predicted by a farm-to-fork model (expressed in units of bacteria per serving) and then applying the dose–response relation $r(x)$ to each sampled value of x produces a frequency distribution of the risk per serving in an exposed population. This information can be displayed in various ways to inform risk-management decision making.

For example, the expected number of illnesses per year in a population, expected illnesses per capita-year in the overall population and for members of sensitive subpopulations, and frequency distributions or upper and lower confidence limits around these expected values are typical outputs of a risk model. If particular decisions are being considered, such as a new standard for the maximum times and/or temperatures at which ready-to-eat meats can be stored before being disposed of, then plotting expected illnesses per year against the decision variables (i.e., maximum times or temperatures, in this example) provides the quantitative links between alternative decisions and their probable health consequences needed to guide effective risk management decision making.

Attribution-Based Risk Assessment and Controversies

In recent years, many efforts have been made to simplify the standard approach to microbial risk assessment just summarized. Because farm-to-fork exposure modeling and valid dose–response modeling can require data that are expensive and time consuming to collect, or that are simply not available when

risk-management decisions must be made, simpler approaches with less burdensome data requirements are desirable. It is tempting to use simple multiplicative models, such as the following:

$$\text{Risk} = \text{exposure} \times \text{dose-response factor} \times \text{consequence} \quad (2)$$

where *risk* is the expected number of excess illness-days per year, *exposure* is measured in potentially infectious meals ingested per year in a population, *dose–response factor* is the expected number of illnesses caused per potentially infectious meal ingested, and *consequence* is measured in illness-days caused per illness.

While such models have attractive simplicity, they embody strong assumptions that are not necessarily valid, and can thus produce highly misleading results. Specifically, the assessment of *dose–response factor* requires attributing some part of the causation of illness-days to *exposure*. Similarly, estimating the change in *dose–response factor* due to an intervention that changes microbial load may require guesswork. There is often no valid, objective way to make such attributions based on available data. The risk assessment model – and, specifically, the attribution of risk to particular food sources – may then become a matter of political and legal controversy.

For example, suppose that the *dose–response factor* is estimated by dividing the observed value of *risk* in a population in one or more years by the contemporaneous values of (*exposure* $\times$ *consequence*). Then, this value will *always* be nonnegative (since its numerator and denominator are both nonnegative). The model thus implies a nonnegative linear relation between *exposure* and *risk*, even if there is no causal relation at all (or is a negative one) between them. In reality, it is a frequent observation that some level of exposure to bacteria in food protects against risk of foodborne illnesses, for example, because of acquired immunity. Thus, the use of a simple multiplicative model implying a necessarily nonnegative linear relation between *exposure* and *risk* may be incorrect, producing meaningless results (or, more optimistically, extreme upper bounds on estimated risks) if the true relation is negative or nonlinear.

For this reason, great caution should be taken when using such simplified risk assessment models. In general, they may be useful in making rapid

calculations of plausible *upper bounds* in certain situations (for example, if the true but unknown dose–response relation between exposure and risk is convex, or upward curving), but should not be expected to produce accurate risk estimates unless they have been carefully validated [2].

Managing Uncertain Food Risks via Quality Principles: HACCP

Even if dose–response relations are uncertain and information needed to quantify microbial loads with accuracy and confidence is not available, it is often possible to apply process quality improvement ideas to control the microbial quality of food production processes. This approach has been developed and deployed successfully (usually on a voluntary basis) using the *hazard analysis and critical control points* (HACCP) approach summarized in Table 1. The main idea of HACCP is to first identify steps or stages in the food production process where bacteria can be controlled, and then to apply effective controls at those points, regardless of what the ultimate quantitative effects on human health risks may be. Reducing microbial load at points where it can be done effectively has proved very successful in reducing final microbial loads and improving food safety.

Discussion and Conclusions

This article has introduced key ideas used to quantify and manage human health risks from food contamination by bacteria. Somewhat similar ideas apply to other foodborne hazards, i.e., risk assessment can be carried out by modeling the flow of contaminants through the food production process (together with any increases or decreases at different steps), resulting in levels of exposures in ingested foods or drinks. These are then converted to quantitative risks using dose–response functions.

The practical successes of the HACCP approach provide a valuable reminder that QRA is not always a prerequisite for effective risk management. It may not be necessary to quantify a risk to reduce it. Reducing exposures at critical control points throughout the food production process can reduce exposure-related risk even if the size of the risk is unknown.

Where QRA can make a crucial contribution is in situations where there is doubt about whether an intervention is worthwhile. For example, QRA can reveal whether expensive risk-reducing measures are likely to produce correspondingly large health benefits. It may be a poor use of resources to implement expensive risk-reducing measures if the quantitative size of risk reduction procured thereby is very small. QRA methods such as farm-to-fork exposure modeling and dose–response modeling [1], or simpler upper-bounding approaches based on multiplicative models [2], can then be valuable in guiding effective

Table 1 Summary of seven HACCP principles^(a)

<i>Analyze hazards.</i>	Potential hazards associated with a food and measures to control those hazards are identified. The hazard could be biological, such as a microbe; chemical, such as a toxin; or physical, such as ground glass or metal fragments.
<i>Identify critical control points.</i>	These are points in a food's production – from its raw state through processing and shipping to consumption by the consumer – at which the potential hazard can be controlled or eliminated. Examples are cooking, cooling, packaging, and metal detection.
<i>Establish preventive measures with critical limits for each control point.</i>	For a cooked food, this might include minimum cooking temperature and time required to ensure the elimination of any harmful microbes.
<i>Establish procedures to monitor the critical control points.</i>	Such procedures might include determining how and by whom cooking time and temperature should be monitored.
<i>Establish corrective actions to be taken when monitoring shows that a critical limit has not been met with</i>	– for example, reprocessing or disposing of food if the minimum cooking temperature is not met with.
<i>Establish procedures to verify that the system is working properly</i>	– for example, testing time-and-temperature recording devices to verify that a cooking unit is working properly.
<i>Establish effective recordkeeping to document the HACCP system.</i>	This would include records of hazards and their control methods, the monitoring of safety requirements, and action taken to correct potential problems. Each of these principles must be backed by sound scientific knowledge: for example, published microbiological studies on time-and-temperature factors for controlling foodborne pathogens.

Managing Infrastructure Reliability, Safety, and Security

Infrastructure and its Social Purpose

Infrastructure typically refers to physical systems and their institutional settings that support social and economic activity, and reliability is essential to meeting this need. Until the early 1980s, infrastructure had received relatively little systematic or comprehensive attention as a unified system. The relative inattention to infrastructure as a distinct area of focus was in part due to the absence of a single political constituency for infrastructure as a whole either in the form of supporters or dissidents. In contrast, many individual infrastructure areas had very active constituencies (e.g., antihighway, antiincinerator, and promass transit groups).

The Meaning of Infrastructure

The way in which infrastructure is defined influences our expectations of its reliability. Ironically, in spite of the inattention to infrastructure, it was reliability that popularized infrastructure as a unified theme in the early 1980s [1]. The term *infrastructure* as it is used today is a relatively recent concept. Prior to the 1980s, the word infrastructure was typically defined in the context of military installations. Tarr [2, p. 4] defines the components of infrastructure as “the sinews of the city: its road, bridge and transit networks; its water and sewer lines, and waste disposal facilities; its power systems; its public buildings; and its parks and recreation areas.” To a large extent infrastructure systems form the “links” and “nodes” that Kevin Lynch identifies as defining the sense of urban places [3]. The common element in these early definitions was a physical facility or system. However, infrastructure goes well beyond a physical dimension, and now has well-recognized economic, social, and political dimensions suitable for a public service. Paralleling the emergence of this broader conceptualization of infrastructure, the field once dominated by the engineering profession now includes many other disciplines [4].

Reliability and Performance

Infrastructure reliability, in its most general sense, refers to whether a system performs as expected; thus performance is central to the concept of reliability and the way in which it is managed (*see Systems Reliability*). The National Research Council (NRC) [5, p. 122] defines reliability as part of performance as “the likelihood that infrastructure effectiveness will be maintained over an extended period of time; the probability that service will be available at least at specified levels throughout the design lifetime of the infrastructure system.” Performance is generally the “carrying out of a task or fulfillment of some promise or claim” with a more specific definition reflective of the specific functions of infrastructure [5, p. 5]. The NRC underscores the relative or contextual nature of performance, that is, “performance must ultimately be assessed by the people who own, build, operate, use, or are neighbors to that infrastructure” [5, p. 5]. Performance is usually measured against benchmarks, guidelines, and standards (*see Benchmark Analysis*).

The Fragmentation of Infrastructure Performance Measures by Sector.

Each type of infrastructure traditionally had its own distinct performance measures for overall reliability. For example, in transportation, roadway performance often emphasized congestion [6] and safety along with many other roadway characteristics [7]. Examples of specific performance measures for congestion and safety are percentage of miles with service levels equal to or less than 0.70 (volume to capacity ratio) and number of fatalities per 100 million vehicle miles of travel, respectively [8, p. 218–219]. Transit measures incorporate operational measures such as mean distance between failures, defined as the number of miles a train travels before it breaks down. Electricity performance was dominated by a long list of operational standards reflected in oversight documents, such as the New York State (NYS) Public Service Commission review of the Queens blackout of 2006 and the special commission report for the massive August 2003 blackout that affected 50 million people in the United States and Canada [9]. Water supply and wastewater infrastructure follow professional guidance as well as regulatory standards established under the Safe Drinking Water Act (SDWA) and the Clean Water Act (CWA), which focus in part on

the capacity or the ability to maintain the required supply and quality of water, and systems that convey water or wastewater often follow professional standards related to leakage rates. Telecommunications is largely measured in terms of a number of different industry and regulatory standards depending on the particular type of telecommunications. The American Society of Civil Engineers (ASCE) maintains an annual scorecard for each individual infrastructure area as a broad measure of performance, and provides an aggregate measure across all of the categories as well. In 2005, the scores ranged from D – for water-related infrastructure sectors to C+ for solid waste, and the aggregate for all sectors was D with an estimated 5-year investment need of \$1.6 trillion (excluding security) [10]. This is an increase over the minimum of \$853 billion estimate (also probably excluding security) cited in 1998 [11]. The ASCE methodology to assess performance uses judgments of an expert panel, based on condition and capacity criteria, and is not risk-based, at least not explicitly.

The Need for Integrating Performance Measures across Infrastructure Sectors. Approaching infrastructure as a unified theme rather than in terms of its component areas is critical to managing reliability, since different types of infrastructures share many things in common. Different areas of infrastructure compete for the same capital investments, labor pools, construction sites, and most of all users or customers. Infrastructure sectors are connected to and are an integral part of economic development in similar ways. For example, unit costs for the provision of infrastructure of any type at a given level of performance are often a function of the type and intensity of land development [12]. Infrastructure technologies share a common problem that abrupt changes can occur as their scale increases and these can influence cost in uneven ways (for example, the transition from septic tanks to wastewater treatment plants; wells to community water supplies). Different infrastructures also have in common “publicness”, that is, they provide public services even though these services might be under private ownership. Finally, different infrastructure sectors often have similar management frameworks, problems, and even metrics in order to achieve reliability though the details may differ.

Another important dimension is that many infrastructures are interrelated both spatially and functionally; e.g., they may be located in the same area.

Since the latter part of the twentieth century, the notion of infrastructure interdependencies, which are fundamental to achieving reliability, security, and safety, has underscored the unity of infrastructure, both functionally and geographically.

Finally, a common framework for all types of infrastructures is needed to incorporate infrastructure characteristics and risks for priority setting and resource allocation. With different metrics for reliability and performance in different infrastructure sectors, this becomes nearly impossible to accomplish. The US Department of Homeland Security (DHS) has underscored the need to use risk-based methods to allocate resources for security, especially with respect to infrastructure [13].

Objectives and Concepts Associated with Reliability

Infrastructure reliability, as a performance concept, has evolved distinctly differently within the different disciplines. Engineers are concerned with the operation of the system. Economists emphasize the efficiency and effectiveness of these operations. Social scientists have underscored public service as a bottom line. Objectives for infrastructure reliability have reflected this wide range of interests, and typically include security, safety, health [14], convenience, comfort, aesthetics, environmental soundness [15], social soundness (including equity, justice, and fairness [16]), and economic and fiscal viability. These objectives often overlap and conflict with one another. They are prioritized differently depending on individual judgments.

Safety and security are considered as a starting point for reliability, since they pertain to basic survival. If the infrastructure reliability objectives listed above have any order at all, safety and security would probably precede and will be a necessary prerequisite for the others. Safety is defined as protection from the threat of death, injury, and loss of property. Security is more subtle than safety, but related to it. Security pertains to the assurance of being protected against catastrophic events such as those posed by natural disasters and terrorism (*see Counterterrorism*). Some concepts fall under both safety and security, such as crime, depending on what the context is. These two concepts will be the focus of the discussion of reliability, since they represent its key features.

Safety

In the decade before *America in Ruins* [1] popularized the condition of US infrastructure and how its reliability was being undermined, many major structures were experiencing massive and often spectacular failures threatening safety that dramatically changed the procedures and processes for measuring and managing infrastructure reliability. The Teton Dam collapse in 1974 initiated the National Dam Inspection Program. Transportation accidents, such as the aviation accidents associated with DC-10s [17, p. 139] provided the foundation for the National Transportation Safety Board (NTSB) as an entity independent of the United States Department of Transportation (DOT) in 1974 (though it had been established in 1967). By the end of 2004, the NTSB had “investigated more than 120 000 aviation accidents and over 10 000 surface transportation accidents – becoming the world’s premier transportation accident investigation agency.” [18, p. vi]. A bridge collapse in 1967 – the Silver Bridge between West Virginia and Ohio killing 46 people [19] led to the establishment of the National Bridge Inspection Program. Several other massive collapses such as the Schoharie Bridge in New York state on April 5, 1987 injuring 10 people fatally [20] and the Mianus Bridge in Connecticut that resulted in the death of three people led to major changes in the way bridges are designed and managed to ensure safety [21]. New, rapidly emerging, and widespread use of infrastructure technologies led to a safety focus. In the area of electric power, safety concerns have arisen in connection with both the availability of electricity and the proximity of facilities to people. Deaths, especially among sensitive populations, have been attributed to blackouts. Deaths have also occurred near distribution systems where stray voltages have caused electrocution.

Security

The management of infrastructure for security was distinct from that of safety. Though safety initially arose as a key focus of reliability, by the early to mid-1990s major terrorist attacks on infrastructure and buildings occurred worldwide, as well as some of the most costly damages to infrastructure and buildings from natural hazards. The 1993 attack on the World Trade Center through its underground parking

facility, the September 11, 2001 attacks *via* aircraft on the World Trade Center that disabled transit and roadways in New York City and the Pentagon in Washington, DC, and a string of terrorist attacks on transit outside of the United States continuing through the twenty-first century all moved infrastructure reliability into a new dimension, that of security. Security meant managing infrastructures with a greater degree of redundancy and flexibility than had been the case before the attacks [22].

As a consequence of the emphasis on security, a subset of infrastructure, “critical infrastructure”, emerged. A number of federal laws, strategies, plans, and programs initiated this effort beginning in the mid-1990s. These arose after a series of rail attacks but well before the September 11, 2001 attacks in New York City and Washington, DC.

Selected Indicators for Security: Infrastructure Concentrations.

Patterns and trends in the location of infrastructure potentially have security implications. Over the past several decades, the extent of infrastructure facilities has grown, paralleled by a concentration of facilities in order to keep the costs down. In order to achieve economies of scale, different types of infrastructure are often colocated. Thus, when one system is disabled, others are also threatened. Examples of these concentrations and their contribution to increasing vulnerability and actual incidence of damage are noteworthy, and occur in

practically every infrastructure sector. At the state level, for example, half of the petroleum facilities are in 4 states, and half of the power plants are in 11 states; half of transit ridership is in 2 states, and half of the auto ridership is in 9 states [26, p. 531–532].

Evidence of the Growing Vulnerability of Infrastructure. In the electricity sector, the number and duration of outage incidents have been increasing in the past decade or so, as per an analysis of incidents in the United States since the 1990s [27]. This phenomenon is largely due to weather-related events. In fact, outages due to weather seem to have surpassed those due to equipment failure in the more recent years, leading one to believe that some of those more conventional equipment-related problems have been solved while some of the more extreme situations related to weather seem to be beyond the ability of infrastructure managers [27].

Infrastructure Interdependencies. Infrastructure systems have grown far more complex. This is in part due to increasing densities in urban areas and increasing demand for infrastructure to meet the needs of suburban area growth. Interdependencies can magnify condition and performance problems beyond what any single system might experience owing to a cascading of impacts [28].

Interdependencies are conceptualized at many different perspectives or scales. Input–output techniques provide interindustry impacts of changes on any one sector such as infrastructure on the rest of the economy at regional and national scales [29]. The development and application of a ratio to the duration of electric power outages relative to duration of the restoration of infrastructure that depends on that electricity in connection with the August 2003 blackout found notable delays in restoration times for infrastructures dependent on electric power [30].

Risk-Based Analytical Approaches

Computation of infrastructure risks from terrorism and natural hazards is a new and emerging field. Some methods are based on risk analysis and decision analysis, while others take alternative approaches. One review of traditional reliability and risk analysis argues that the newer risks require different analytical approaches [31]. A number of analytical tools are

being used, and these can be categorized for the purpose of discussion in terms of whether they aim to identify (a) the likelihood of an attack or alternatively (b) the consequences should such an attack occur (though some studies employ both of these areas).

Likelihood and Form of Attack

The issue of estimating likelihood or form of attack has been approached using analytical techniques, such as probabilistic and statistical forecasting models and game theory, and many involve scenario construction. Game theory, for example, has been applied to the problem of what defenders should do in the face of attackers as a guide to allocating defensive resources [32]. Models incorporating attack scenarios that reflect the form or type of an attack have been based on systems analysis and probability using risk analysis and decision trees, which are then used to identify and rank threats [33] the reference [27].

Consequence Assessment

For consequence assessment, for example, statistical models were developed and applied to historical trends in electric power failures to estimate the expected consequences of potential future outages, on duration, megawatts lost, and customers affected [27]; similarly spatial distributions and time trends were also analyzed for oil and gas pipeline failures and electric power failures, as a basis for inputs to risk management [34], and ongoing research by the same team estimates consequences of oil and gas infrastructure failure such as deaths, injuries, property loss, value of product lost, and cleanup and recovery costs applying statistical models of outage trend data.

Analyses of economic consequences of massive infrastructure disruptions have also been conducted using a variety of modeling techniques. Regional econometric models have been used to estimate the economic impacts of a loss of electric power in a single state, New Jersey [35]. Methods have been developed and applied to estimate the magnitude of business loss, death, injury, and congestion from a statistical model of outage events for individual urban areas, and combined with average dollar estimates for each of the loss categories to obtain overall economic impacts [36]. Input–output analysis has been used to estimate impacts across infrastructure and other economic categories of various infrastructure

disruptions [37]. Computable General Equilibrium (CGE) analysis has been used to estimate economic impacts of outages for a variety of infrastructure areas, for example, water systems [38]. Case-based approaches to combined risk and economic consequence analysis provide important analytical tools. A scenario-based analysis that combined probability of alternative modes of attack, severity of the attack, and its consequences in terms of economic impact was undertaken for a dirty bomb in a large port area [39].

Conclusions

The meaning of infrastructure reliability and two of its key components, safety and security, has changed over time as the goals of infrastructure systems and services have changed and as our understanding of system vulnerabilities has changed, especially in light of the relatively newer threats of natural hazards and terrorism. The integration of information technologies into infrastructure has also altered reliability concepts, adding opportunities to improve reliability as well as another layer of complexity and potential vulnerability [40]. The need for infrastructure to provide critical emergency services for both response during a catastrophe and recovery in the period following these events is an area of growing importance. In order to manage the prevention, recovery, and rebuilding after catastrophes, we need to adapt our understanding and measurement of infrastructure performance in the face of these threats.

Objectives for infrastructure reliability are still highly fragmented and differ widely not only among different infrastructure sectors, many of which are interrelated, but also within a single infrastructure. Different infrastructure sectors evaluate reliability with different levels of information quality and types of standards and protocols. This fragmentation particularly becomes an issue when managing the risks of interdependencies among infrastructures.

Measuring infrastructure reliability, safety, and security are now critical aspects of managing infrastructure, including protecting infrastructure assets by prioritizing them for resource allocation [41]. Risk-based decision making has become a distinct element of security policy and resource allocation [13, 42], yet, a considerable debate exists as to the nature of risks faced by critical infrastructures, how these

risks should be quantified and the tools available to do so, at what geographic scale analyses should be undertaken, and how results are to be used as a basis for prioritization schemes [43]. In particular, the sensitivity of the methodology to changes in assumptions and variables remains a future challenge. The basis for distributing these funds through the Homeland Security Grant Program (HSGP) in part is based on risk assessment methodologies to guide the allocation of funds by urban area as well as for specific types of infrastructure. The funds available under HSGP totaled \$1.7 billion in FY 2006, and according to a recent report by the US Government Accountability Office [44] represented a decline in funding of 14% over the previous fiscal year. Through FY 2007, the DHS has indicated that a total of \$1.5 billion was granted under the Infrastructure Protection Program with \$445 million for FY 2007 alone [45].

Irrespective of safety and security, a growing threat to the continued integrity of infrastructure underscored by persistent low quality levels [10] is declining levels of funding relative to need. In many infrastructure sectors, gap analyses conducted over the years have supported the existence of this divide. The 2008 funding cycle similarly shows that this gap is not likely to be closed in the near future, with critical cuts occurring in transit and water infrastructure [46]. This represents expenditures primarily for standard capital investment, and does not reflect patterns and trends in security funding. These two streams of investment need to be combined. Achieving reliability encompasses many criteria, one of which is security, and solutions to many of the security needs are likely to be solutions to other objectives for reliable infrastructure as well.

Managing Risks of Consumer Products

Each year consumer products are involved in tens of millions of injuries and tens of thousands of fatalities in the United States [1]. Primary responsibility for risk management rests with the companies that create and manufacture products. Most developed countries have also established government agencies that provide regulatory oversight for consumer products. In the United States, the Consumer Product Safety Commission (CPSC) maintains regulatory jurisdiction over more than 15 000 types of consumer products, including toys, cribs, power tools, cigarette lighters, and household chemicals. The National Highway Traffic Safety Administration provides regulatory oversight for motor vehicles, and the US Food and Drug Administration regulates safety of food, drugs, medical devices, biologics, cosmetics, and radiation-emitting products.

Proper consideration of public safety can improve product design and development, management of product quality during manufacturing, and monitoring of field performance during use by consumers. Formal tools of quantitative risk assessment add value by improving decision making at each of these stages.

Product Design and Development

Product characteristics and statistical analysis of historical data on product-related injuries and deaths can inform safety assessment of a product design before it is manufactured and distributed. Alternative designs can be developed and tested to reduce the risk of particular injury mechanisms. Examples include the design of children's toys and consumer electronics to reduce choking hazards and electric shock risks, respectively.

The most widely used source of US data on product-related injuries is the National Electronic Injury Surveillance System (NEISS) [2] operated by CPSC. NEISS is a national probability sample of hospitals from which patient information is collected for every emergency visit involving an injury associated with consumer products. From this sample, which includes more than 375 000 cases per year, the total

number of product-related injuries treated in hospital emergency rooms nationwide can be estimated.

Each NEISS case provides information on the date of injury, type of product, gender and age of the injured party, diagnosis (e.g., laceration and fracture), body part(s) involved, disposition (e.g., admitted, treated, and released), and locale (e.g., home, work, and school) where the injury occurred. A short narrative describes the incident and associated injuries. Manufacturers can use data sources such as NEISS to understand the types and frequencies of injuries that occur in association with the use of a consumer product.

Estimating not only the frequency but also the risk of injury requires some measure of the opportunity for injury (i.e., the exposure). For example, risk assessments of all-terrain vehicles use data on riding hours from both industry- and government-sponsored surveys of owners [3]. Comparative risk analyses (*see Comparative Risk Assessment*) of other recreational products may use information from the National Sporting Goods Association [4] on levels of participation in related activities. For studies of burn risk from home appliances, the Energy Information Administration's Residential Energy Consumption Survey provides data on the number of US households having these appliances [5].

Risk Management in Product Manufacturing

Unintended declines in the production quality of consumer items can pose safety hazards to consumers, increase failure rates, and shorten product life, which, in turn, causes unexpected financial burdens and potential legal liabilities to manufacturers. At the beginning of the production process, companies may implement acceptance sampling plans to ensure the quality of raw materials or components produced internally or by suppliers [6, 7]. The acceptable quality limits (AQLs) used in such plans can be chosen on the basis of a quantitative risk assessment. Standard tools for statistical process control – such as N_p , $\bar{X}$ -bar, and R charts – are routinely deployed by manufacturers to provide checks on quality throughout their production processes [8, 9]. A motivating principle is that successful business operations require continuous effort to reduce variation in process outputs. End-of-line

testing is typically performed before manufacturers approve products for shipping to customers. In some industries (e.g., pharmaceuticals), such testing may be required by government regulation [10].

Monitoring of Field Performance

Information about the performance of a product after release to consumers comes from field returns, warranty programs (*see Warranty Analysis*), and customer complaints. Records of incidents involving failure of a product during operation, with or without associated injuries to consumers, typically include information such as model and serial number of the unit, production date or date code, incident date, and sales location. In monitoring field performance, a manufacturer needs to determine whether an adverse change has occurred and, if so, assess its implications for product reliability and safety. If a background level of event risk is accepted, statistical methods can determine whether adverse events can be explained by random variation or require attention [11]. Production, shipping, and sales records typically provide the raw data for such analyses.

Confirmation of a problem raises a series of questions: How bad is it? Is it getting worse? Do field data point to a particular production period or facility? A quantitative risk assessment can address these questions using statistical estimation and hypothesis testing. Risk analysts review the available information about the production history and seek changes in time period, plant, process, equipment, design, or supplier that are associated with subsequent problems. Parametric statistical models are frequently used to fit time-to-failure distributions in engineering applications (*see Lifetime Models and Risk Assessment*).

Strategies for Risk Mitigation

When an unacceptable safety hazard is found to exist by manufacturers and/or regulators, the finding prompts corrective action. Product recalls require identification of the units affected, typically by time or source of production, and determination of whether affected units will be repaired or replaced. Increasing globalization of the world economy challenges manufacturers and regulators of consumer products, as a product may contain components from different nations and be sold to markets all over the world.

The process for implementing corrective action varies from country to country. In the United States, CPSC adopted in 1997 a “Fast Track Product Recall Program” [12] for reports filed according to Section 15(b) of the Consumer Product Safety Act (CPSA). This program requires manufacturers, distributors, and retailers of consumer products to notify the commission of certain defects, unreasonable risks, or noncompliance with voluntary or mandatory standards. Under the CPSC Fast Track program, the staff refrains from making a preliminary determination when firms report and, within 20 working days, implement an acceptable corrective action plan. The plan submitted to CPSC must describe the recall action (refund, repair, or replace) that the company will take to eliminate the identified risk, and provide sufficient information on the product design, incident, and testing to allow the CPSC staff to determine whether the proposed action can correct the identified problem.

Tools for Risk Communication

An effective risk assessment must link measured levels of risk to specific corrective actions. Supporting tools have been developed, particularly in the European Union [13].

A community rapid information exchange system known as RAPEX assesses the risk of potentially hazardous consumer products by first considering (a) the probability of health damage from regular exposure, as characterized in Table 1, and (b) the severity of injury from the product, as characterized in Table 2. Depending on the probability and severity of damage, as illustrated in Figure 1, the RAPEX method then classifies the overall gravity of an adverse outcome on a five-point ordinal scale ranging from very low to very high. The final judgment of whether the risk requires corrective action considers three additional factors: (a) the vulnerability of people exposed to the product, particularly children and the elderly, (b) whether the hazard is obvious to nonvulnerable adults, and (c) whether the product has adequate warnings and safeguards. The RAPEX methodology is sometimes viewed as the preferred approach in countries adopting a risk-averse approach to consumer product safety based on such rough scoring [13].

An alternative tool, the Belgian risk matrix, qualitatively rates the level of exposure to the hazardous

Table 1 Risk classification for RAPEX method

Probability of health/safety damage from regular exposure to hazardous product	Probability of hazardous product		
	1%	10%	100%
Hazard is always present and health/safety damage is likely to occur in foreseeable use	Medium	High	Very high
Hazard may occur under one improbable or two possible conditions	Low	Medium	High
Hazard only occurs if several improbable conditions are met	Very low	Low	Medium

Table 2 Severity classification for RAPEX method

Slight	Serious	Very serious
<2% incapacity, usually reversible and not requiring hospital treatment Minor cuts, minor fractures, minor burns, sprains	2–15% incapacity, usually irreversible requiring hospital treatment Serious cuts, loss of a finger or toe, damage to sight, damage to hearing, moderate burns	>15% incapacity, usually irreversible Death, loss of limbs, loss of sight, loss of hearing, serious burns (>25%)

product, the probability of hazard occurrence, and the seriousness of the consequences [13]. Numerical scores are assigned to each level of these factors. The product of the three factors yields a quantitative

risk score, a corresponding characterization of risk on a five-point ordinal scale ranging from slight to very high, and identification of the action required to mitigate the assessed level of risk.

Risk assessment of consumer products for the GPSD

This procedure is proposed to assist companies when deciding whether a specific hazardous situation caused by a consumer product requires notification to the authorities

Figure 1(a) is used to determine the gravity of the outcome of a hazard, depending on the severity and probability of the possible health/safety damage (see the text in Example).

Figure 1(b) is used to determine the rating of the gravity of risk depending on the type of user and, for nonvulnerable adults, whether the product has adequate warnings and safeguards and whether the hazard is sufficiently obvious.

Example (indicated by the arrows above)

A chain saw user has suffered a badly cut hand and it is found that the chain saw has an inadequately designed guard that allowed the user's hand to slip forward and touch the chain. The company's assessor makes the following risk assessment.

Figure 1(a)–The assessment of probability is high because the hazard is present on all products and may occur under certain conditions. The assessment of severity is serious so the overall gravity rating is high.

Figure 1(b)–The chain saw is for use by nonvulnerable adults, and presents an obvious hazard but with inadequate guards.

The high gravity is therefore intolerable, so a serious risk exists.

Figure 1 Outline of RAPEX risk assessment methodology: (a) risk estimation and (b) grading of risk

Figure 2 Slovenian nomograph, sample risk assessment of cots

The Slovenian nomograph [13] considers four factors: the availability of the product on the market, the capability of an average adult to recognize product defects and potential misuse, the probability of hazard occurrence, and the maximum potential injury resulting from the hazard. Construction of the nomograph involves developing scales for each factor and placing the scales in positions relative to one another that correspond to a particular weighting of the factors. Figure 2 illustrates the placement of the scales and use of the nomograph to assess various risks posed to consumers from cots. As shown, the risk assessor draws a line through the maximum injury and occurrence probability scales, as well as a tie line, at which point the risk assessor draws an intersecting line through the hazard recognition scale. This line can be extended to intersect a number line from which the assessor obtains a risk score. The inclusion of product availability is optional and would provide an estimate of the societal risk associated with the product.

Summary

Although consumer products are required to be safe, safety does not mean zero risk. A safe product is one that has reasonable risks, given the magnitude of the benefit expected and the alternatives available. In managing consumer product risk, quantitative risk assessment and associated statistical methods are used to frame substantive issues in terms of estimable quantities and testable hypotheses, to extract information on product performance from data on field incidents and manufacturing records, and to communicate findings to upper management, regulatory authorities, and consumers.

Markov Modeling in Reliability

Many life-critical systems are required to operate without a system failure for a given period of time. Examples are nuclear, aerospace, spacecraft, and other such systems. Redundancy (*see Reliability Growth Testing; Reliability Optimization*) is often used to achieve high reliability. Such systems are fault tolerant since they can continue to function even when one or more of the components have failed. The term *reliability* (*see Mathematics of Risk and Reliability: A Select History*) is generally used to express certain degree of assurance that a system will operate successfully in a specified environment, during a certain time period. Reliability is the probability that a system performs a specified service throughout a specified interval of time.

Reliability of a system is related to its lifetime. Let T be the random variable representing the length of the lifetime of a system. Then, the reliability for a system is defined as follows:

Definition Reliability of a system, denoted by $R(t)$, is the probability that the system functions until time t . Then

$$R(t) = P(T > t) = 1 - F(t), \quad t \geq 0 \quad (1)$$

where $F(t)$ is the cumulative distribution function of the random variable T . $F(t)$ gives the probability that the lifetime does not exceed t , i.e.,

$$F(t) = P(T \leq t) = 1 - R(t) \quad (2)$$

Therefore, $F(t)$ is often called unreliability of the system.

Another important function related to life distribution is the instantaneous failure rate or hazard function $h(t)$ (*see Default Risk; Mathematical Models of Credit Risk; Reliability Data; Lifetime Models and Risk Assessment*). This is the instantaneous failure rate of a component that has survived t units of time, i.e.,

$$h(t) = \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \frac{F(t + \Delta t) - F(t)}{P(T > t)} = \frac{f(t)}{R(t)} \quad (3)$$

where $f(t)$ is the probability density function of T . The product $h(t)\Delta t$ represents the conditional

probability that a component having survived to age t will fail in the interval $(t, t + \Delta t)$.

Finally, we introduce the concept of mean time to failure (MTTF) (*see Imprecise Reliability*). MTTF is the average length of time until failures and is given as

$$MTTF = E[T] = \int_0^\infty t f(t) dt = \int_0^\infty R(t) dt \quad (4)$$

Reliability modeling is a useful technique to abstract the dynamic behavior of computer, communications, aerospace, nuclear and similar systems to predict their reliability. To perform the reliability modeling, we must be familiar with the reliability characteristics of the system and its components, the failure modes and their effect on the system. A reliability model is constructed to represent the reliability characteristics, and predict the system reliability.

Reliability analysis of the systems is typically performed using one of the two methods, combinatorial modeling and Markov modeling (*see Credit Migration Matrices; Imprecise Reliability*). Combinatorial modeling methods such as fault trees (*see Expert Judgment; Latin Hypercube Sampling; Canonical Modeling*), reliability graphs, and reliability block diagrams (*see Systems Reliability*) are applicable to cases where the system can be broken down into series and parallel combination of its components. These model types capture conditions that make a system fail in terms of the structural relationships between the system components. The main limitation of the combinatorial methods is that they cannot be used to model system repairs or dynamic reconfigurations of the system. For more complex systems that cannot be represented as series and parallel combination of events, and also exhibit complicated interactions between the components, the technique of Markov modeling is employed. Various dependencies between the components are captured by Markov models. For the systems with large number of components, the number of states can grow prohibitively large. This results in state space explosion and hence the large Markov models. Hierarchical model (*see Bayesian Statistics in Quantitative Risk Assessment; Geographic Disease Risk; Meta-Analysis in Nonclinical Risk Assessment*) composition is applied to avoid large Markov models [1, 2].

For evaluating the reliability of the complex systems, formulating an analytic model can be quite

cumbersome. Also, in practice, isolating the effect of various parameters on a system, while holding the others as constants, requires exploring a variety of scenarios. It is economically infeasible to build several such systems. Simulation offers an attractive mechanism for reliability evaluation and the study of the influence of various parameters on the failure behavior of the system. In [3], several algorithms are developed for computing the reliability of fault tolerant systems. However, in this article, we emphasize on Markov modeling in reliability for the complex systems.

Markov Modeling

Markov models consider the system states and the possible transitions between these states. The states in a fault tolerant system are distinguished as operational or failed, depending on the available system functionality. The basic assumption in Markov model is that the system is memoryless, that is, the transition probabilities are determined only from the present state and not by the history. For reliability analysis with Markov models, these conditions are specified by the assumption of exponential distributions for failure and repair times. A *state transition diagram* is a directed graph representation of system states, transition between states, and transition rates. These diagrams contain sufficient information for developing the state equations. The effect of changes in the model parameters can be easily investigated. For detailed discussion on Markov processes, readers are referred to [4, 5]. The following examples show how Markov model can be used to obtain the measure of interest such as reliability and MTTF for the parallel redundant system.

Example of Parallel Redundant System

We consider Markov reliability model of a parallel redundant system with two components [4]. Assume

Figure 1 State transition diagram for the parallel redundant system

that the time to failure of a component is exponentially distributed with failure rate λ . The system has a single repair facility. Time to repair of a component is exponentially distributed with parameter μ . The system fails when both the components fail and no recovery is possible. Let the state of the system be defined as the number of components in working condition. The state space is $\{0, 1, 2\}$. State “0” is an absorbing state since the system does not move to other states once it is in state “0”. The state transition diagram is given in Figure 1.

Let $P_j(t)$ be the probability that system is in state j at time t . From the state transition diagram, the system of differential equations can be written as

$$\frac{d}{dt}P_2(t) = -2\lambda P_2(t) + \mu P_1(t) \quad (5)$$

$$\frac{d}{dt}P_1(t) = 2\lambda P_2(t) - (\lambda + \mu)P_1(t) \quad (6)$$

$$\frac{d}{dt}P_0(t) = \lambda P_1(t) \quad (7)$$

Suppose the system is in state 2 at time $t = 0$ i.e., $P_2(0) = 1$; $P_1(0) = P_0(0) = 0$. The above systems of equations can be solved using the technique of Laplace transform. Hence, taking Laplace transform on both sides of the above equations and using the initial condition, we get

$$s\hat{P}_2(s) - 1 = -2\lambda\hat{P}_2(s) + \mu\hat{P}_1(s) \quad (8)$$

$$s\hat{P}_1(s) = 2\lambda\hat{P}_2(s) - (\lambda + \mu)\hat{P}_1(s) \quad (9)$$

$$s\hat{P}_0(s) = \lambda\hat{P}_1(s) \quad (10)$$

On solving the above equations for $P_0(s)$, we get

$$\hat{P}_0(s) = \frac{2\lambda^2}{s[s^2 + (3\lambda + \mu)s + 2\lambda^2]} \quad (11)$$

or

$$\hat{P}_0(s) = \frac{2\lambda^2}{s(s + s_1)(s + s_2)} \quad (12)$$

where

$$s_1, s_2 = \frac{(3\lambda + \mu) \pm \sqrt{\lambda^2 + 6\lambda\mu + \mu^2}}{2} \quad (13)$$

Let the random variable T denote the time to failure of the system. Then $P_0(t)$ gives the probability that the system has failed at or before time t . Therefore,

reliability of the system (that is, probability of nonfailure) is given as

$$R(t) = 1 - P_0(t) \quad (14)$$

The cumulative distribution function (cdf) $F(t)$ of T is given as

$$F(t) = P(T \leq t) = 1 - R(t) \quad (15)$$

Differentiating equation (15), the probability density function of T , denoted by $f(t)$, is given by

$$f(t) = \frac{d}{dt}(-R(t)) = \frac{d}{dt}P_0(t) \quad (16)$$

Taking Laplace transform on both sides of equation (16), we get

$$\hat{f}(s) = s\hat{P}_0(s) = \frac{2\lambda^2}{(s + s_1)(s + s_2)} \quad (17)$$

Taking inverse Laplace transform (see **Ruin Probabilities: Computational Aspects**), we get

$$f(t) = \frac{2\lambda^2}{s_1 - s_2} (e^{-s_2 t} - e^{-s_1 t}) \quad (18)$$

Therefore, reliability $R(t)$ of the system is given by

$$R(t) = \int_t^\infty f(t) dt = \frac{2\lambda^2}{s_1 - s_2} \left[\frac{e^{-s_2 t}}{s_2} - \frac{e^{-s_1 t}}{s_1} \right] \quad (19)$$

Using equation (4), MTTF of the system is obtained as:

$$\begin{aligned} E[T] &= \int_0^\infty (1 - F(t)) dt = \int_0^\infty R(t) dt \\ &= \frac{2\lambda^2(s_1 + s_2)}{s_1^2 s_2^2} \end{aligned} \quad (20)$$

On substituting the values of s_1 and s_2 , we get

$$MTTF = \frac{3}{2\lambda} + \frac{\mu}{2\lambda^2} \quad (21)$$

Example of Parallel Redundant System with Imperfect Coverage

This is a modified form of the example discussed in the section titled "Example of Parallel Redundant System". In this case, it is assumed that not

Figure 2 State transition diagram of the system with imperfect coverage

all faults are recoverable and there is a coverage factor "c", denoting the conditional probability that the system recovers, given that a fault has occurred. The state transition diagram of this example is shown in Figure 2. For this state transition diagram, the system of differential equations are written as

$$\begin{aligned} \frac{d}{dt}P_2(t) &= -2\lambda c P_2(t) \\ &\quad - 2\lambda(1-c)P_2(t) + \mu P_1(t) \end{aligned} \quad (22)$$

$$\frac{d}{dt}P_1(t) = -(\lambda + \mu)P_1(t) + 2\lambda c P_2(t) \quad (23)$$

$$\frac{d}{dt}P_0(t) = \lambda P_1(t) + 2\lambda(1-c)P_2(t) \quad (24)$$

Assume that, initially the system is in state 2, so that $P_2(0) = 1$, $P_0(0) = P_1(0) = 0$. Taking Laplace transform on both sides of above equations and applying the initial condition, we get

$$\begin{aligned} s\hat{P}_2(s) - 1 &= -2\lambda c \hat{P}_2(s) \\ &\quad - 2\lambda(1-c)P_2(s) + \mu \hat{P}_1(s) \end{aligned} \quad (25)$$

$$s\hat{P}_1(s) = 2\lambda c \hat{P}_2(s) - (\lambda + \mu) \hat{P}_1(s) \quad (26)$$

$$s\hat{P}_0(s) = \lambda \hat{P}_1(s) + 2\lambda(1-c) \hat{P}_2(s) \quad (27)$$

On solving the above system of equations for $\hat{P}_0(s)$, we get

$$\hat{P}_0(s) = \frac{2\lambda}{s} \left[\frac{s + \lambda + \mu - c(s + \mu)}{s(s + 2\lambda)(s + \lambda + \mu) - 2\lambda\mu c} \right] \quad (28)$$

In this system, the cdf of T , the time to system failure, is given by

$$F(t) = P_0(t) \quad (29)$$

Taking Laplace transform and using the initial condition, we get

$$\hat{f}(s) = s\hat{P}_0(s) = 2\lambda \left[\frac{s + \lambda + \mu - c(s + \mu)}{s(s + 2\lambda)(s + \lambda + \mu) - 2\lambda\mu c} \right] \quad (30)$$

Without using inverse Laplace transformations to obtain distribution of T , $E[T]$ can be obtained directly using the moment generating property of Laplace transforms. We have,

$$E[T] = -\frac{d}{ds} \hat{F}(s) \Big|_{s=0} \quad (31)$$

On solving this, we get the following expression for MTTF,

$$MTTF = E[T] = \frac{\lambda(1 + 2c) + \mu}{2\lambda(\lambda + \mu(1 - c))} \quad (32)$$

The above two examples illustrate Markov modeling technique to predict the system reliability.

Limitations of Markov Models

Even though the Markov modeling method is widely used to analyze the system reliability, it does have several limitations. First, the Markov model becomes too complex if all the possible system states are considered. It leads to the state space explosion. A system having n components may require up to 2^n states in a Markov chain representation. Several approaches such as state truncation, fixed point iteration and hierarchical decomposition techniques are proposed [1, 6]. Second, stiffness is the important problem faced in Markov modeling. For example, in a highly reliable system, with very efficient maintenance, the failure rates are very low and repair rates are high. Their ratio will be of several orders of magnitude and lead to loss of precision. For the stiffness problem, improving the solution results will involve a combination of techniques including better algorithms and acceptable approximations [7, 8]. Finally, the major objection to the use of Markov models in the reliability analysis is the assumption

that sojourn time in any state is exponentially distributed. This does not always realistically represent the observed distribution. One way to deal with non-exponential distributions is the phase type approximation, which consists of modeling a distribution with a set of states and transitions between those states such that the sojourn time in each state is exponentially distributed [4].

Conclusions

The Markov model has been used in several applications such as computer and communication, economics, banking systems, and aviation systems. In this article, we have explained how Markov modeling can be used to evaluate the reliability of the complex systems. Examples are provided to illustrate the technique. However, the application of the Markov model is subject to several limitations such as largeness, stiffness, and the assumption of exponential distributions for failure and repair times. Improving the computer algorithms, use of fast computers, and use of high level modeling formalisms such as stochastic Petri nets tries to fill the gap between Markov modeling and system design specification.

Mathematical Models of Credit Risk

Mathematical modeling of credit risk is concerned with constructing formal models of time evolution of credit ratings (credit migrations, *see Credit Risk Models*) in a pool of credit names, and with studying various properties of such models. In particular, this involves modeling and studying default times and their functionals. Because of the space limitation we do not discuss credit migrations in this article, and we limit the discussion to default events only. As a matter of fact, we only discuss mathematical modeling pertaining to a single obligor, and thus, pertaining to a single default time. Discussion of issues regarding mathematical modeling of multiple default times (*see Default Correlation; Hazard and Hazard Ratio*) and their stochastic dependence, deserves a separate article.

Default time (*see Simulation in Risk Management; Copulas and Other Measures of Dependency*) is a strictly positive random variable, say τ . For simplicity, we assume that τ is continuously distributed on $(0, \infty)$. Typically, one is interested in computing expectations of various functionals of default time, conditioned on available information. Thus, the role of the conditional law of τ , given the information available on the market at current time t , is of main importance. In this context, it is frequently sufficient to study the rate of occurrence of the default, that is, the conditional probability that the default occurs in a small time interval dt , knowing that the default has not occurred before t and perhaps also knowing some other relevant information. However, in the general case when H hypothesis is not satisfied, that knowledge – i.e., the knowledge of the intensity – is not sufficient.

Typical functionals of the default time are defaultable bonds. In what follows, a defaultable zero-coupon (DZC) bond (*see Default Correlation*), with maturity T , pays 1 monetary unit at time T if $\tau > T$, and it pays 0 otherwise. A corporate bond, with recovery process R , pays 1 monetary unit at time T if no default occurs by time T , and it pays R_t at time t if the default occurs at time t , for $t \leq T$. More generally, a generic defaultable claim (X, R, τ) pays X at maturity in case default does not occur prior to or at maturity, and it pays the recovery R_t at default

time, when $\tau = t < T$. We denote by $H_t = \mathbb{I}_{\tau \leq t}$ the default process, by $B(t, T)$ the price of a default-free zero-coupon bond (*see Credit Migration Matrices*) with maturity T , by $\beta_t = \exp(-\int_0^t r_s ds)$ the discount factor, and by $\beta_t^T = \beta_T / \beta_t = \exp(-\int_t^T r_s ds)$. In the case of a deterministic interest rate, $B(t, T) = \beta_t^T$, and in the case of stochastic interest rate $B(t, T) = \mathbb{E}_{\mathbb{Q}}(\beta_t^T | \mathcal{F}_t) = \mathbb{E}_{\mathbb{Q}}(\exp(-\int_t^T r_s ds) | \mathcal{F}_t)$, where $\mathbb{Q}$ is the risk-neutral probability, or the pricing measure, and where $\mathcal{F}_t$ represents conditioning information.

An important class of functionals of default times are credit derivatives (*see Credit Value at Risk*), an example of which is credit default swap (CDS) (*see Credit Risk Models; Simulation in Risk Management*). CDS is a liquid contract referencing a default time τ , and providing a protection against financial loss associated with this default time. The party selling the protection (seller of the CDS) promises to pay to the protection buyer (buyer of the CDS) a protection payment δ_t in case $\tau = t \leq T$, where T is the maturity of the CDS. In return, the protection buyer agrees to pay to the protection seller a premium, which is paid until default time or until maturity of the contract, whichever occurs first. In the financial practice, the premium is paid according to some discrete tenor schedule. For the purpose of mathematical modeling and study of CDSs, it is convenient to assume that the premium is paid continuously in time, at rate κ , which is termed *CDS spread* or *CDS annuity*.

There are two main approaches to modeling default times: the structural approach and the reduced approach, also known as *hazard process approach*.

Structural Models

Classical versions of these models of default assume that the market reveals all needed information about default time *via* prices of related liquid securities, such as prices of equity issued by the default prone obligor. In other words, the default is announced by observation of the prices of traded instruments. Typically, in these models, credit spreads, representing the differentials between yields on defaultable bonds and yields on default-free bonds (treasury bonds), narrow to zero when time approaches the bond's maturity. This, however, is not a phenomenon observed in the market. Another questionable property of classical structural models is that in these models the

default time is predictable, that is, it is announced by a sequence of economic events that can be observed in the market. This property is frequently contradicted by market reality (recall Enron's collapse).

The typical example of a structural model, is the model in which the default time is defined as $\tau = \inf\{t : S_t \leq a\}$, where S represents price process of the underlying equity, assumed to be continuous. There are various mathematical models of the evolution of S , the simplest of which is the geometric Brownian motion model (see **Insurance Pricing/Nonlife; Weather Derivatives**),

$$dS_t = S_t(\mu dt + \sigma dW_t) \quad (1)$$

In this model, pricing and hedging defaultable claims of payoff $h(S_T)\mathbb{1}_{T < \tau}$ reduces to classical hedging of barrier contingent claims. In particular, the price of a DZC is that of a digital barrier option.

Modeling of dependence between several default times is straightforward with the classical structural models, as it amounts to modeling correlation between the processes that trigger the default; typically, this reduces to modeling correlation between Brownian motions. However, closed forms are difficult (or even impossible) to obtain for more than two defaults.

Reduced Models

In these models the default event arrives by surprise; the surprise can be total, or partial. In mathematical terms, this means that the default time is not predictable.

We assume here that there exists a financial market, which we call the full market or the defaultable market. The information flow in this defaultable market is modeled in terms of the so-called full filtration $\mathbf{G} = (\mathcal{G}_t, t \geq 0)$.

Filtration $\mathbf{G}$ consists of two filtrations: $\mathbf{G} = \mathbf{F} \vee \mathbf{H}$. The reference filtration $\mathbf{F}$ corresponds to the default-free component of our market (default-free market or primary market, for short), and is, for simplicity, assumed to be the Brownian filtration. The default filtration $\mathbf{H}$ provides the information regarding occurrence of the default time. Thus, at any time t , the information available in this market consists of the information $\mathcal{F}_t$ provided by the default-free market, and of the knowledge of H_t , that is, knowledge of whether the default has occurred by time t or not.

In what follows, we assume that all random objects are constructed on some probability space $(\Omega, \mathcal{G}, \mathbb{P})$ where $\mathbb{P}$ is the historical probability and where σ -algebra $\mathcal{G}$ is such that $\mathcal{G}_t \subset \mathcal{G}$ for all t . The major modeling issue is modeling of the conditional survival probabilities $\tilde{\mathbb{P}}(\tau > T | \mathcal{F}_t)$, where $\tilde{\mathbb{P}}$ is a probability measure equivalent to $\mathbb{P}$; in particular, we can have $\tilde{\mathbb{P}} = \mathbb{P}$, or $\tilde{\mathbb{P}} = \mathbb{Q}$ – the pricing measure.

Toy Model: τ Independent of F

The total surprise under probability $\tilde{\mathbb{P}}$ occurs when the survival probability does not depend on the conditioning information $\mathcal{F}_t$, that is, for all $t \geq 0$ we have that

$$G^{\tilde{\mathbb{P}}}(t, T) := \tilde{\mathbb{P}}(\tau > T | \mathcal{F}_t) = \tilde{\mathbb{P}}(\tau > T) \quad (2)$$

Since $\mathcal{F}_t$ is the information provided by the default-free market, the above means that the default time is independent of the prices of default-free securities under probability measure $\tilde{\mathbb{P}}$. Thus, we can interpret the total surprise case saying that default-free market provides no information regarding the possible default. Of course, this is not a reasonable hypothesis from the practical perspective, although it needs to be mentioned, that, in practice, it is frequently assumed that default intensity is deterministic, which implies that the default time comes as total surprise. We shall adopt this hypothesis temporarily to illustrate the basic techniques underlying reduced modeling in this very simple set up.

To simplify the notation, we shall write $G^{\tilde{\mathbb{P}}}(t)$ in place of $G^{\tilde{\mathbb{P}}}(t, t) = \tilde{\mathbb{P}}(\tau > t)$. Accordingly, we denote by $F^{\tilde{\mathbb{P}}}$ the cumulative probability distribution of τ , i.e.,

$$F^{\tilde{\mathbb{P}}}(t) = \tilde{\mathbb{P}}(\tau \leq t) = 1 - G^{\tilde{\mathbb{P}}}(t) \quad (3)$$

and we assume that $F^{\tilde{\mathbb{P}}}(t) < 1$ for all $t \geq 0$. Additionally, we assume in the text that follows that $F^{\tilde{\mathbb{P}}}$ is differentiable, and we denote its derivative (the p.d.f. of τ) by $f^{\tilde{\mathbb{P}}}$. Note that for $t < T$, we have

$$\begin{aligned} \tilde{\mathbb{P}}(\tau > T | \tau > t) &= \frac{\tilde{\mathbb{P}}(\tau > T)}{\tilde{\mathbb{P}}(\tau > t)} = \frac{1 - F^{\tilde{\mathbb{P}}}(T)}{1 - F^{\tilde{\mathbb{P}}}(t)} \\ &= \frac{G^{\tilde{\mathbb{P}}}(T)}{G^{\tilde{\mathbb{P}}}(t)} \end{aligned} \quad (4)$$

Hazard Function. Let $\Gamma^{\tilde{\mathbb{P}}}(t) = -\ln(1 - F^{\tilde{\mathbb{P}}}(t))$ be the hazard function (see **Default Risk; Reliability Growth Testing; Lifetime Models and Risk Assessment; Markov Modeling in Reliability**) of τ . In view of our assumptions, we see that it is an increasing function of the form $\Gamma^{\tilde{\mathbb{P}}}(t) = \int_0^t \gamma^{\tilde{\mathbb{P}}}(s) ds$, where

$$\gamma^{\tilde{\mathbb{P}}}(s) ds = \frac{f^{\tilde{\mathbb{P}}}(s)}{1 - F^{\tilde{\mathbb{P}}}(s)} \quad (5)$$

It can be easily shown that the process

$$M_t^{\tilde{\mathbb{P}}} = H_t - \int_0^{t \wedge \tau} \gamma^{\tilde{\mathbb{P}}}(s) ds \quad (6)$$

is a martingale (see **Mathematics of Risk and Reliability: A Select History**) with respect to the filtration generated by process H , under probability $\tilde{\mathbb{P}}$. The superscript $\tilde{\mathbb{P}}$ in the above notations was meant to emphasize that the respective functions and processes depend on the choice of measure $\tilde{\mathbb{P}}$. To simplify the notation, we shall omit the superscript whenever $\tilde{\mathbb{P}} = \mathbb{Q}$. So, for example, we shall write $G(t)$ in place of $G^{\mathbb{Q}}(t)$.

If the primary market is arbitrage free and complete, there exists a unique risk-neutral probability, say $\mathbb{Q}^F$. In the present setting, one cannot hedge defaultable claims using the primary market only, i.e., using the default-free assets traded in the primary market. In particular, measure $\mathbb{Q}^F$ cannot be used to price defaultable securities. For that, we need to know the risk-neutral probability corresponding to the entire defaultable market, that is, a probability measure $\mathbb{Q}$ under which discounted prices of all traded securities, default-free and defaultable, are $\mathbf{G}$ -martingales. Typically, such a measure is calibrated from the observed prices of all underlying securities traded in the defaultable market. Of course, to avoid arbitrage opportunities, the restriction of $\mathbb{Q}$ to the primary market must be equal to $\mathbb{Q}^F$.

Defaultable Zero-Coupon Bonds. We assume here that the default time τ is independent of $\mathbf{F}$ under $\mathbb{Q}$. If a treasury bond of maturity T and a DZC of maturity T are traded in the market at prices $B(t, T)$ and $D(t, T)$ respectively, then the risk-neutral probability of survival can be deduced from these prices. To see this, we first observe that $D(T, T) = \mathbb{1}_{T < \tau}$, and therefore,

$$\begin{aligned} \mathbb{E}_{\mathbb{Q}}(D(T, T) | \mathcal{F}_T) &= \mathbb{E}_{\mathbb{Q}}(\mathbb{1}_{T < \tau} | \mathcal{F}_T) = \mathbb{Q}(T < \tau) \\ &= G(T) \end{aligned} \quad (7)$$

Thus, since in view of the first fundamental theorem of asset pricing, the value of a DZC is the conditional expectation of discounted payoff under $\mathbb{Q}$, we obtain

$$\begin{aligned} D(t, T) &= \mathbb{E}_{\mathbb{Q}}(D(T, T) \beta_T^t | \mathcal{G}_t) \\ &= \mathbb{1}_{t < \tau} \frac{\mathbb{E}_{\mathbb{Q}}(D(T, T) \beta_T^t | \mathcal{F}_t)}{\mathbb{E}_{\mathbb{Q}}(\mathbb{1}_{t < \tau} | \mathcal{F}_t)} \\ &= \mathbb{1}_{t < \tau} \frac{\mathbb{E}_{\mathbb{Q}}(\mathbb{E}_{\mathbb{Q}}(D(T, T) | \mathcal{F}_T) \beta_T^t | \mathcal{F}_t)}{\mathbb{E}_{\mathbb{Q}}(\mathbb{1}_{t < \tau} | \mathcal{F}_t)} \\ &= \mathbb{1}_{t < \tau} \frac{G(T)(\beta_T^t | \mathcal{F}_t)}{G(t)} \\ &= \mathbb{1}_{t < \tau} \frac{G(T)B(t, T)}{G(t)} \end{aligned} \quad (8)$$

In particular,

$$\frac{D(0, T)}{B(0, T)} = G(T) \quad (9)$$

Deterministic Interest Rate and Deterministic Recovery. In the particular case of deterministic interest rate, the dynamics of D are

$$\begin{aligned} dD(t, T) &= -\frac{G(T)}{G(t)} B(t, T) dH_t \\ &\quad - (1 - H_t) B(t, T) \frac{G(T)}{G(t)^2} dG(t) \\ &\quad + (1 - H_t) \frac{G(T)}{G(t)} r(t) B(t, T) dt \\ &= r(t) D(t, T) dt - D(t^-, T) (dH_t - \gamma(t) dt) \\ &= r(t) D(t, T) dt - D(t^-, T) dM_t \end{aligned} \quad (10)$$

More generally, the price of a corporate bond with deterministic recovery function R is

$$\begin{aligned} D^{(R)}(t, T) &= \mathbb{1}_{t < \tau} \left(\frac{G(T)}{G(t)} B(t, T) \right. \\ &\quad \left. + \frac{1}{G(t)} \int_t^T B(t, s) R(s) dF(s) \right) \end{aligned} \quad (11)$$

and thus, the risk-neutral dynamics of such a bond are

$$\begin{aligned} dD^{(R)}(t, T) &= (r(t) D^{(R)}(t, T) - R(t) \gamma(t) (1 - H_t)) \\ &\quad \times dt - D^{(R)}(t^-, T) dM_t \end{aligned} \quad (12)$$

The value at time t of a defaultable payoff $\mathbb{1}_{\tau > T} h(S_T)$ is

$$\begin{aligned} & \mathbb{E}_{\mathbb{Q}}(\mathbb{1}_{\tau > T} h(S_T) \beta_T^t | \mathcal{G}_t) \\ &= \mathbb{1}_{t < T} B(t, T) \frac{\mathbb{E}_{\mathbb{Q}}(\mathbb{1}_{\tau > T} h(S_T) | \mathcal{F}_t)}{\mathbb{Q}(\tau > t)} \end{aligned} \quad (13)$$

In this toy model, the independence assumption and the hypothesis that the interest rate is deterministic implies that

$$\begin{aligned} & \mathbb{E}_{\mathbb{Q}}(\mathbb{1}_{\tau > T} h(S_T) \beta_T^t | \mathcal{F}_t) \\ &= B(t, T) \mathbb{E}_{\mathbb{Q}}(h(S_T) \mathbb{E}_{\mathbb{Q}}(\mathbb{1}_{\tau > T} | \mathcal{F}_T) | \mathcal{F}_t) \\ &= B(t, T) G_T \mathbb{E}_{\mathbb{Q}}(h(S_T) | \mathcal{F}_t) \end{aligned} \quad (14)$$

Stochastic Interest Rate. In the case of stochastic interest rate, we assume that the risk-neutral dynamics of the default-free ZC (zero-coupon) bond are

$$dB(t, T) = B(t, T) (r(t) dt + \sigma(t, T) dW_t) \quad (15)$$

Then, the dynamics of D are

$$\begin{aligned} dD(t, T) &= -\frac{G(T)}{G(t)} B(t, T) dH_t \\ &\quad - (1 - H_t) B(t, T) \frac{G(T)}{G(t)^2} dG(t) \\ &\quad + (1 - H_t) \frac{G(T)}{G(t)} dB(t, T) \\ &= D(t, T) (r(t) dt + \sigma(t, T) dW_t) \\ &\quad - D(t^-, T) (dH_t - \gamma(t) dt) \\ &= r(t) D(t, T) dt \\ &\quad + D(t^-, T) (\sigma(t, T) dW_t - dM_t) \end{aligned} \quad (16)$$

Pricing defaultable contingent claims. We now consider a defaultable contingent claim with payoff $\mathbb{1}_{\tau > T} h(S_T)$ and whose the price is

$$\begin{aligned} & \mathbb{E}_{\mathbb{Q}}(\mathbb{1}_{\tau > T} \beta_T^t h(S_T) | \mathcal{G}_t) \\ &= \mathbb{1}_{t < \tau} G(t)^{-1} G(T) \mathbb{E}_{\mathbb{Q}}(h(S_T) \beta_T^t | \mathcal{F}_t) \\ &= \mathbb{1}_{t < \tau} \mathbb{Q}(\tau > T | t > \tau) \mathbb{E}_{\mathbb{Q}}(h(S_T) \beta_T^t | \mathcal{F}_t) \\ &= \mathbb{1}_{t < \tau} \exp\left(-\int_t^T \gamma(s) ds\right) \\ &\quad \times \mathbb{E}_{\mathbb{Q}}(h(S_T) \beta_T^t | \mathcal{F}_t) \end{aligned} \quad (17)$$

Thus, the price of the defaultable contingent claim is the product of the price of the corresponding default-free payoff and of the conditional survival probability. A more interesting way of writing this equality is

$$\begin{aligned} & \mathbb{E}_{\mathbb{Q}}(\mathbb{1}_{\tau > T} \beta_T^t h(S_T) | \mathcal{G}_t) = \mathbb{1}_{t < \tau} \\ & \mathbb{E}_{\mathbb{Q}}\left(h(S_T) \exp\left(-\int_t^T (r_s + \gamma(s)) ds\right) \middle| \mathcal{F}_t\right) \end{aligned} \quad (18)$$

which shows that the price of a defaultable contingent claim is the price of the same promised payoff $h(S_T)$ in a world where the interest rate is $r + \gamma$.

Hedging defaultable contingent claims. It is instructive to give a simple example of hedging of a defaultable claim with payoff $\mathbb{1}_{\tau > T} h(S_T)$. We assume that the primary market is complete. Let $\hat{h}_t = \mathbb{E}_{\mathbb{Q}}(\mathbb{1}_{\tau > T} \beta_T^t h(S_T) | \mathcal{G}_t)$ be the discounted price of the defaultable claim, and $\hat{h}_t^F = \mathbb{E}_{\mathbb{Q}}(h(S_T) \beta_T^t | \mathcal{F}_t)$ be the discounted price of the (default-free) payoff $h(S_T)$. Then, $\hat{h}_t = \mathbb{1}_{t < \tau} \frac{G(T)}{G(t)} \hat{h}_t^F = L_t \hat{h}_t^F$ with $L_t = \mathbb{1}_{t < \tau} \frac{G(T)}{G(t)}$. In particular, if $\hat{D}(t, T)$ and $\hat{B}(t, T)$ denote the discounted prices of DZC and ZC, respectively, then $\hat{D}(t, T) = L_t \hat{B}(t, T)$. Using that $dL_t = L_t^- dM_t$, one gets

$$\begin{aligned} d\hat{h}_t &= -\hat{h}_t^F L_t^- dM_t + L_t d\hat{h}_t^F \\ &= \frac{1}{\hat{B}(t, T)} (\hat{h}_t^F d\hat{D}(t, T) \\ &\quad - L_t \hat{h}_t^F d\hat{B}(t, T)) + L_t d\hat{h}_t^F \end{aligned} \quad (19)$$

Since the primary market is complete, we have $d\hat{h}_t^F = \varphi_t d\hat{S}_t$, where $\hat{S}$ denotes the discounted price of the primary security, and where φ is a predictable process. The following portfolio, constructed on the DZC, the ZC, and the underlying asset

$$\left(\frac{1}{\hat{B}(t, T)} \hat{h}_t^F, -\frac{1}{\hat{B}(t, T)} \hat{h}_t^F L_t, L_t \varphi_t \right) \quad (20)$$

is self-financing (see **Alternative Risk Transfer**) since

$$\begin{aligned} & \frac{1}{\hat{B}(t, T)} \hat{h}_t^F d\hat{D}(t, T) - \frac{1}{\hat{B}(t, T)} \hat{h}_t^F d\hat{B}(t, T) \\ & \quad + L_t \varphi_t d\hat{S}_t = d\hat{h}_t \end{aligned} \quad (21)$$

and thus it is a replicating portfolio for the defaultable claim $\mathbb{1}_{\tau > T} h(S_T)$. This portfolio enjoys the remarkable property that the amount of money invested in the DZC is equal to the value of the claim $h(S_T)$.

CDS. CDS contracts are the most liquid, single name credit derivatives. We illustrate here the mathematical modeling of CDS price process in the simple set up of our toy model.

The (ex-dividend) price at time $t \in [s, T]$ of a CDS contract started at s , with rate κ and protection payment $\delta(\tau)$ at default time, where δ is a function, equals

$$S_t(\kappa) = \mathbb{1}_{t < \tau} \frac{1}{G(t)} \left(\int_t^T B(t, u) \delta(u) G(u) \gamma(u) du - \kappa \int_t^T B(t, u) G(u) du \right) \quad (22)$$

The dynamics of the ex-dividend price $S_t(\kappa)$ on $[s, T]$ are

$$dS_t(\kappa) = -S_{t-}(\kappa) dM_t + (1 - H_t) G_t^{-1} \beta_t^{-1} dm_t + (1 - H_t)(r_t S_t(\kappa) + \kappa - \delta(t) \gamma(t)) dt \quad (23)$$

where the $(\mathbb{Q}, \mathbf{F})$ -martingale m is given by the formula

$$m_t = \mathbb{E}_{\mathbb{Q}} \left(\int_0^T \beta_u^{-1} \delta(u) G(u) \gamma(u) du - \kappa \int_0^T \beta_u^{-1} G(u) du \middle| \mathcal{F}_t \right) \quad (24)$$

Analogous formulae can be obtained in the case of forward credit default swap (CDS) contracts.

General Case

We shall only give here a flavor of mathematical modeling in case of partial surprise. Much more information can be found in the references provided below.

A partial surprise is when one can extract some information from the market, i.e., when $G(t, T) = \mathbb{Q}(\tau > T | \mathcal{F}_t) \neq \mathbb{Q}(\tau > T)$, so that the conditional probabilities $G(t, T)$ form an $\mathbf{F}$ -adapted process.

In fact, the process $G_t = G(t, t) = \mathbb{Q}(\tau > t | \mathcal{F}_t)$ contains all the relevant information about default time, in the sense that

$$G(t, T) = \mathbb{Q}(\tau > T | \mathcal{F}_t) = \mathbb{E}_{\mathbb{Q}}(G_T | \mathcal{F}_t) \quad (25)$$

We now make the assumption that $G_t > 0$. Recall that the full information in our defaultable market is carried by the filtration $\mathbf{G}$. The related, risk-neutral survival probabilities are before time t

$$\begin{aligned} \mathbb{Q}(\tau > T | \mathcal{G}_t) &= \mathbb{1}_{t < \tau} \frac{\mathbb{Q}(\tau > T | \mathcal{F}_t)}{\mathbb{Q}(\tau > t | \mathcal{F}_t)} \\ &= \mathbb{1}_{t < \tau} \frac{\mathbb{E}_{\mathbb{Q}}(G_T | \mathcal{F}_t)}{G_t} \\ &= \mathbb{1}_{t < \tau} \frac{G(t, T)}{G_t} \end{aligned} \quad (26)$$

If τ is an $\mathbf{F}$ stopping time, then $G_t = \mathbb{1}_{\tau > t}$; in this the primary market provides complete information on τ (this is the case of classical structural approach).

The price process of a DZC is now

$$\begin{aligned} D(t, T) &= \mathbb{1}_{t < \tau} \frac{\mathbb{E}_{\mathbb{Q}}(\mathbb{1}_{\tau > T} \beta_T | \mathcal{F}_t)}{\beta_t G_t} \\ &= L_t \beta_T^t \mathbb{E}_{\mathbb{Q}}(G_T | \mathcal{F}_t) \end{aligned} \quad (27)$$

where $L_t = \mathbb{1}_{t < \tau} G_t^{-1}$ is a $\mathbf{G}$ -martingale. It is important to observe that, in full generality, the process G is not decreasing and that its martingale part is of some importance in the pricing methodology. Hedging strategies can be obtained and, obviously, depend strongly on the choice of the dynamics of the traded securities. In particular, the amount of money invested in the defaultable asset is equal to the value of the claim, as soon as the value of the defaultable asset is null after default.

Mathematics of Risk and Reliability: A Select History

Writing the history about any topic is both challenging and demanding. It is demanding because one needs to acquire a broad perspective about the topic, a perspective that generally comes over time and experience. The challenge of writing history comes from the matter of what to include and what to omit. There is the social danger of offending those readers who feel that their work should have been mentioned, but was not. However, the moral obligation of excluding the works of those who are no more with us is much greater. Writers of history must therefore confront the challenge and draw a delicate line. This task is made easier with the passage of time, because the true impact of a signal contribution is felt only after time has elapsed. By contrast, the impact of work that is incremental or marginal can be judged immediately. It is with the above in mind that the history that follows is crafted. The word “select” in the title of this contribution is deliberate; it reflects the judgment of the authors. Hopefully, the delicate line mentioned before, has been drawn by us in a just and honorable manner. All the same, our apologies to those who may feel otherwise, or those whose works we have accidentally overlooked.

Introduction

From a layperson’s point of view, a viewpoint that predates history, the term *risk* connotes the possibility that an undesirable outcome will occur. However, the modern technical meaning of the term *risk* is different. Here, *risk* is the sum of the product of the *probabilities* of all possible outcomes of an action and the *utilities* (see **Longevity Risk and Life Annuities; Multiattribute Value Functions; Clinical Dose–Response Assessment**) (or consequences) of each outcome. Utilities are numerical values of consequences on a zero to one scale. Indeed, utilities are probabilities and obey the rules of probability [1, p. 56]. They encapsulate one’s preferences between consequences. Thus the notion of risk entails the twin notions of probability and utility. Some adverse outcomes are caused by the failure

or the malfunctioning of certain entities, biological or physical. For such adverse outcomes, the probability of failure of the entity in question is known as the *entity’s unreliability*; its *reliability* (see **Managing Infrastructure Reliability, Safety, and Security; Repair, Inspection, and Replacement Models; Reliability Data; Extreme Values in Reliability; Markov Modeling in Reliability**) is the probability of nonfailure for a specified period of time. In the biomedical contexts, wherein the entity is a biological unit, the term *survivability* (see **Multistate Systems; Multiattribute Value Functions**) is used instead of reliability. Thus, assessing reliability (or survivability) is *de facto* assessing a probability, and *reliability theory* pertains to the methods and techniques for doing such assessments.

The linkage between reliability and risk is relatively new [2]. It is brought about by the point of view that the main purpose of doing a reliability analysis is to make sound decisions about preventing failure in the face of uncertainty. To the best of our knowledge, the first document that articulates this position is Barlow *et al.* [3]. Thus we see that probability, utility, risk, reliability, and decision making are linked, with probability playing a central role, indeed the role of a germinator. Our history of risk and reliability must therefore start with a history of probability.

Probability is a way to quantify uncertainty. Its origins date back to sixteenth-century Europe and discussions about its meaning and interpretation continue until the present day. For a perspective on these, the review articles by Kolmogorov [4] and Good [5] are valuable. The former wholeheartedly subscribes to probability as an objective *chance*, and the latter makes the point that probability and chance are distinct concepts. The founding fathers of probability were not motivated by the need to quantify uncertainty; they were more concerned with action than with interpretation. This enables us to divide the history of probability into three parts: until 1750, 1750–1900, and from 1900. These reflect, in our opinion, three reasonably well-defined periods of development of the mathematics of uncertainty which we label as foundations, maturation, and expansion of applicability.

Some excellent books on the history of probability are by Hald [6, 7], Stigler [8], and von Plato [9]. Since the history of probability is the background for the history of risk and reliability, a reading of these and the exhaustive references therein should provide risk

and reliability analysts a deeper appreciation of the foundations of their subject.

Until 1750: The Foundations of Probability

Insurance was the first field in which the traditional notion of risk had to be quantified. Its use can be traced back four millennia to ancient China and Babylonia, where traders took on the risks of the caravan trade by taking out loans that were repaid if the goods arrived. The ancient Greeks and Phoenicians used marine insurance, while the Romans had a form of life insurance that paid for the funeral expenses of the holder. However, there is no evidence that insurance was a common practice and indeed it disappeared with the fall of the Roman Empire. It took the growth of towns and trade in Renaissance Europe, where risks such as shipwreck, losses from fire, and even kidnap ransom worried the wealthy, for insurance to develop once again.

It was the development of probability in the seventeenth century that finally saw the foundation for the mathematics of risk, and where our brief history can really begin. We should mention first that the mathematization of uncertainty can be traced back to Gioralimo Kardano (1501–1575). However, it was the short correspondence between Pierre de Fermat (1608–1672) and Blaise Pascal (1623–1662) that began the development of modern probability theory. Their correspondence concerned a gambling question called *The Problem of Points*, which is to determine the fair bet for a game of chance in which each player has an equal chance of winning, and the bet is won as soon as either player wins the game a predetermined number of times. The difficulty arises if the number of games to win is different for each player; Fermat’s and Pascal’s correspondence led to a solution. Meanwhile, a contemporary of both, Christiaan Huygens (1629–1695), was one of the earliest scientists to think mathematically about risk. He was motivated by problems in annuities, which at that time were common means for states and towns to borrow money. Huygens wrote up the solution of Fermat and Pascal, and is thus credited with publishing the first book on probability theory [10].

Without the benefit of Fermat’s and Pascal’s theory, Graunt produced the first mortality table by decade [11], from which he concluded that only 1% of the population survived to 76 years. Table 1 shows

Table 1 The table records the percentages of people to die in the first 6 years of life and each decade after to 76 years

Of 100 [“quick conceptions”]	
there dies within the first 6 years	36
The next 10 years, or <i>decad</i>	24
The second decad	15
The third decad	9
The fourth	6
The next	4
The next	3
The next	2
The next	1
[“perhaps but one surviveth 76”]	

Reproduced from [11]. Thomas Roycroft, 1662

this brilliant if unsophisticated effort; see Seal [12] for a discussion of its use.

Graunt’s work happened at the time when property insurance as we know it today began. Following the Great Fire of London in 1666, which destroyed about 13 000 houses, Nicholas Barbon opened an office to insure buildings. In 1680, he established England’s first fire insurance company, “The Fire Office”, to insure brick and frame homes; this also included the first fire brigade. Edmond Halley constructed the first proper mortality table, based on the statistical laws of mortality and compound interest [13]. The table was corrected by Joseph Dodson in 1756, making it possible to scale the premium rate to age; previously, the rate had been the same for all ages.

The idea of a fair price was linked to probability by Jacob Bernoulli (1654–1705), work that was published posthumously by his nephew Nicholas [14]. This work is important because it was the first substantial treatment of probability, and contained the general theory of permutations and combinations, the weak law of large numbers, as well as the binomial theorem. What interested Bernoulli was to apply the Fermat–Pascal idea of a fair bet to other problems where the idea of probability had meaning. He argued that opinions about any event occurring or not were analogous to a game of chance where betting on a certain outcome led to a fair bet. The fair bet then represents the certainty that one attaches to an event occurring. This analogy between games of chance and one’s opinions also appears to have been made at the time of Fermat and Pascal [15]. The law of large numbers was particularly important for this argument because Bernoulli realized that, in practical problems, fair prices could not be deduced exactly

and approximations would have to be found. This allowed him to justify approximating the probability of an event by its relative frequency. Thus, in Bernoulli's ideas we see parts of the two currently dominant interpretations of probability: subjective degree of belief and relative frequency.

The relative frequency idea was further developed by de Moivre [16], who proposed the ideas of independent events, the summation rule, the multiplication rule, and the central limit theorem. This connection between fair prices and probability is the basis for insurance pricing. Bernoulli's and de Moivre's work came during a period of rapid development of the insurance market, spurred on by the growth of maritime commerce in the seventeenth and eighteenth centuries. We have seen that fire insurance had been available since the Great Fire of London, but up to the eighteenth century, most insurance was underwritten by individual investors who stated how much of the loss risk they were prepared to accept. This concept continues to this day in Lloyd's of London, having its beginnings in Edward Lloyd's coffeehouse around 1688 in Tower Street, London, which was a popular meeting place for the shipping community to discuss insurance deals among themselves. Soon after the publication of Bernoulli's work, corporations began to engage in insurance. They were first chartered in England in 1720, and in 1735, the first insurance company in the American colonies was founded at Charleston, SC, by 1750 all the basic ideas of probability necessary for quantifying risk – probability distributions, expected values and the idea of fair price, and mortality – were in place, and were in use in insurance.

1750–1900: Probability Matures

Post-1750, the first notable name is that of Thomas Bayes (1702–1761) and his famous essay on inverse probability [17, 18]. His main contribution was to articulate on the multiplication rule that allows conditional probabilities to be computed from unconditional ones; vitally, this permitted Laplace (1749–1827) to derive the law of total probability and Bayes' law. In contrast to de Moivre, Laplace thought that probability was a rational belief and the rules of probability and expectation followed naturally from this interpretation [19, 20].

Poisson (1741–1840) did much work on the technical and practical aspects of probability, and

greatly expanded the scope and applications of probability. His main contribution was a generalization of Bernoulli's theorem; his seminal work [21] also introduced the Poisson distribution. While Poisson agreed with Laplace's rational belief interpretation of probability, criticisms of this view were raised during second half of the nineteenth century. John Venn (1834–1923) revived the frequency interpretation of probability, hinted at by Bernoulli; however, he took it further to state that frequency was the starting point for defining probability [22].

We note that little attempt had been made so far to quantify the consequences of adverse events through utility and hence to manage risks in a coherent manner. However, we note two developments. First, the idea of utility did arise through Daniel Bernoulli in 1738 and utilitarian philosophers such as Bentham (1748–1832). They proposed rules of rationality that stated individuals desire things that maximize their utility, where positive utility is defined as the tendency to bring pleasure, and negative utility is defined as the tendency to bring pain [23]. Second, the industrial revolution meant that manufacturing and transport carried far graver risks than before, and we do see the first attempts at risk management through regulation. In the United Kingdom, the Factory Act of 1802 (known as the *Health and Morals of Apprentices Act*) started a sequence of such acts that attempted to improve health and safety at work. Following a rail accident that killed 88 people in Armagh, Northern Ireland, the Regulation of Railways Act 1889 made fail-safe brakes as well as block signaling mandatory.

All the main areas of insurance – life, marine, and fire insurance – continued to grow throughout this period. After 1840, with the decline of religious prejudice against the practice, life insurance entered a boom period in the United States. Many friendly or benefit societies were founded to insure the life and health of their members. The close of the nineteenth century finally allows us to say something about mathematical reliability theory; Pearson [24] named the *exponential distribution* for the first time.

From 1900 to the Present: Utility and Reliability Enter

The first half of the twentieth century saw the beginning of the modern era of probability;

Kolmogorov (1903–1987) axiomized probability and in doing so freed it from the confusions of interpretation [25]. This period also saw many developments in the frequency interpretation of probability, and several advances in subjective probability. Von Mises (1883–1953) wrote a paper extolling the virtues of the frequentist interpretation of probability [26]. Together with the work of Karl Pearson (1857–1936) and Fisher (1890–1962), methods of inference under the frequency interpretation of probability became the dominant approaches to data analysis and prediction.

However, at about the same time there were breakthrough developments in the subjective approach to statistical inference and decision making. Noteworthy among these were the work of Ramsey [27] who proposed that subjective belief and utility are the basis of decision making and the nonseparability of probability from utility. Jeffreys' (1891–1986) highly influential book on probability theory combined the logical basis of probability with the use of Bayes' law as the basis of statistical inference [28]. At about this time, de Finetti (1906–1985), unaware of Ramsey's work, adopted the latter's subjectivistic views to produce his seminal work on probability [29], later translated into English [30]. De Finetti is best remembered for the above writings, and his bold statement that *Probability Does Not Exist!*

The period 1900–1950 also saw the laying of the foundations of modern utility theory, from which a prescription for normative decision making comes about. The mathematical basis of today's quantitative risk analysis is indeed normative decision theory. Impetus for a formal approach to utility came from von Neumann and Morgenstern [31] with its interest in rational choice (*see Group Decision*), game theory (*see Managing Infrastructure Reliability, Safety, and Security; Risk Measures and Economic Capital for (Re)insurers; Game Theoretic Methods*), and the modeling of preferences (*see Group Decision; Multiattribute Value Functions*). This was brought to its definitive conclusion by Savage [32], who proposed a system of axioms that linked together the ideas of Ramsey, de Finetti, and von Neumann and Morgenstern. Readable accounts of Savage's brilliant work are in DeGroot [33] and Lindley [1], two highly influential voices in the Bayesian approach to statistical inference (*see Bayesian Statistics in Quantitative Risk Assessment*) and decision making. Not to be overlooked is the 1950 treatise

of Wald (1902–1950) whose approach to statistical inference was decision theoretic [34]. However, unlike that of Savage, Wald's work did not entail the use of subjective prior probabilities (*see Longevity Risk and Life Annuities; Reliability Data; Bayesian Statistics in Quantitative Risk Assessment; Subjective Probability*) on the states of nature.

Hardly mentioned up to now is the mathematical and the statistical theory of reliability. This is because it is only in the 1950s and the 1960s that reliability emerged as a distinct field of study. The initial impetus of this field was driven by the demands of the then newer technologies in aviation, electronics, space, and strategic weaponry. Some of the landmark events of this period are: Weibull's (1887–1961) advocacy of the Weibull distribution for metallurgical failure [35, 36], the statistical analysis of failure data by Davis [37], the proposal of Epstein and Sobel [38] that the exponential distribution be used as a basic tool for reliability analysis, the work of Grenander [39] on estimating the failure rate function and the book of Gumbel [40] on the application of the theory of extreme values for describing failures caused by extremal phenomena (*see Large Insurance Losses Distributions; Risk Measures and Economic Capital for (Re)insurers; Extreme Value Theory in Finance*) such as crack lengths, floods, hurricanes, etc., the approach of Kaplan and Meier [41] (*see Detection Limits; Individual Risk Models; Estimation of Mortality Rates from Insurance Data*) for estimating the survival function under censoring, and the introduction in Watson and Wells [42] of the notion of burn-in. Some, though not all, of this work was described in what we consider to be the first few books on reliability – Bazovsky [43], Lloyd and Lipow [44], and Zelen [45]. Initially, the statistical community was slow to embrace the Weibull distribution as a model for describing random failures; indeed the *Journal of the American Statistical Association* rejected Weibull's 1951 paper. This is despite the fact that the Weibull distribution is a member of the family of extremal distributions [46]. Subsequently, however, the popularity of the Weibull grew because of the papers of Lieblien and Zelen [47], Kao [48, 49], and later the inferential work of Mann [50–52]. Today, along with the Gaussian and the exponential distributions, the Weibull is one of the most commonly discussed distributions in statistics.

Whereas the emphasis of the works mentioned above has been on the statistical analysis of lifetime data, progress in the mathematical and probabilistic aspects was also made during the 1950s and 1960s. A landmark event is the work by Drenick [53] on the failure characteristics of a complex system with the replacement of failed units. It started a line of research in reliability that focused on the probabilistic aspects of components and systems; in a similar vein is a book by Cox [54]. The next major milestone was the paper by Birnbaum *et al.* [55] on the structural representation of systems of components; inspiration for this work can be traced to the classic paper of Moore and Shannon [56] on reliable relays. This was followed by the paper of Barlow *et al.* [57] on monotone hazard rates (*see Statistics for Environmental Toxicity*). This work was highly influential in the sense that it spawned a generation of researchers who explored the probabilistic and statistical aspects of monotonicity from different perspectives. Fault trees (*see Systems Reliability; Markov Modeling in Reliability; Expert Judgment*) also appeared during this decade [58]. Much of this work is summarized in the two books of Barlow and Proschan [59, 60]. There were other notable developments during the late 1960s and mid-1970s, some on the probabilistic aspects, and the others on the statistical aspects. With regard to the former, Marshall and Olkin [61] proposed a multivariate distribution with exponential marginals for describing dependent lifetimes. The noteworthy features of their work are that the distribution was motivated using arguments that are physically plausible, and that its properties bring out some subtle aspects of probability models. At about the same time, Esary *et al.* [62] proposed a notion of dependence that they called *association*. This notion was motivated by problems of system reliability assessment, and the generality of the idea was powerful enough to attract the attention of mathematical statisticians and probabilists to develop it further.

During this period, and perhaps earlier than that, there was important work in reliability also done in the Soviet Union. Indeed, Kolmogorov [4] in his expository papers on statistics, often used examples from reliability and life length studies to motivate his material. Important stochastic process methods were developed, such as in Markov processes and queueing theory, under Gnedenko (1912–1995). The book by Gnedenko *et al.* [63], and the more recent review by

Ushakov [64], gives a perspective on the Soviet work in reliability.

Some other developments in that period were the papers of Cox [65], and of Esary *et al.* [66] and the book by Mann *et al.* [67]. Cox's highly influential paper provided a means for relating the failure rate with covariates. A similar strategy was used in Singpurwalla [68], in the context of *accelerated testing*. The paper by Esary *et al.* on shock models and wear processes was remarkable in two respects. The first is that it addressed a phenomenon of much interest to engineers and produced some elegant results. Second, it paved the way for using stochastic processes to obtain probability models of failure (*see Structural Reliability; Reliability Integrated Engineering Using Physics of Failure; Probabilistic Risk Assessment*) [69]. The book by Mann *et al.* integrated the probabilistic and statistical techniques used in reliability that were prevalent at that time, and by doing so it created a template for the subsequent books that followed. The book was also the first of its kind to make a case for using Bayesian methods for reliability assessment.

Subsequent to the mid-1970s, interest in reliability as an academic discipline took a leap and several books and papers began to appear, and are continuing to appear today. Notable among the former are the books by Lawless [70], Martz and Waller [71], Nelson [72, 73], Gertsbakh [74], Crowder *et al.* [75], Meeker and Escobar [76], Aven and Jensen [77], Singpurwalla and Wilson [78], Hoyland and Rousand [79], and Saunders [80]. With the exception of Martz and Waller [71] and Singpurwalla and Wilson [78], the statistical paradigm guiding the material in the above books has been sample theoretic (i.e., non-Bayesian). In terms of signal developments during the period, two notable ones seem to be Natvig's [81] suggestion to consider multistate systems, and the consideration of subjective Bayesianism in reliability. The latter was triggered by Barlow's interpretation of decreasing failure rates caused by subjective mixing [82], and brought to its conclusion by Gurland and Sethuraman [83]; also see the discussion in Lynn and Singpurwalla [84] of Block and Savits [85]. The book by Spizzichino [86] is an authoritative treatment of the generation of subjective probability models for lifetimes based on *exchangeability* (*see Combining Information; Repair, Inspection, and Replacement Models*).

Some other developments in reliability have come about from the biostatistical perspective of survival analysis. Notable among these are Ferguson's [87] advocacy of the *Dirichlet process* for survival analysis, and Aalen's [88] point process perspective and the martingale approach to modeling lifetimes. The former has been exploited by Sethuraman [89], and the latter by Pena and Hollander [90] and Hollander and Pena [91] in a variety of contexts that are germane to reliability.

To conclude, the last 60 years have seen two trends in risk. First of all, the idea of risk has spread to many other fields outside the traditional areas of insurance and actuarial science. It is now an important idea in medicine, public health, law, science, and engineering. Secondly, driven by its increasing use and by the growth of computing and data-collecting power, increasingly complex quantifications of risk and reliability have been made to make better use of increasing quantities of data; reliability and risk models, inference and prediction with those models, and numerical methods have all advanced enormously. Since the 1960s, in particular, the literature on reliability, risk, and survival analysis has grown in journals that cover statistics, philosophy, medicine, engineering, law, finance, environment, and public policy. Annual conferences on risk in all these subject areas have been held for the last 30 years. In addition to these two trends, we might add that the magnitude of the risks being quantified and managed has increased over the last century; environmental pollution, intensive food production, and the nuclear industry being examples. The same trends in reliability theory can be discerned as those in risk: the spread of application into new fields and the impact of increasing computing power and availability of data. It is worth comparing seminal books on statistical reliability of the 1960s such as Bazovsky [43] and Barlow and Proshan [59] with that of the current decade [2] to see how much the field has changed.

The debate over the interpretation of probability, and uncertainty quantification more generally, continues. The important work of Savage [32], DeGroot [33], and de Finetti [30] publicized the justifications for the laws of probability through their interpretation as a subjective degree of belief. This, along with the practical development of the necessary numerical tools, has increased the use of subjective probability and Bayesian inference in the last 30 years. The strong link between risk,

reliability, and the mathematical tools of probability and decision making, that has existed for 400 years, looks set to continue.

Mercury/Methylmercury Risk

The toxicity of mercury vapor has been known since ancient times, and Bernadino Ramazzini described the occupational health risks 300 years ago. The risks of environmental contamination were dramatically illustrated in the 1960s and 1970s by poisoning incidents in Minamata (Japan) and in Iraq. The current focus is on the risks of neurotoxic damage due to the presence of methylmercury in freshwater fish and seafood. Recent risk assessments include those of the UN Environment Program [1] and the US Environmental Protection Agency [2], and these sources may be consulted for further information and additional references.

Mercury in the environment originates from both natural and anthropogenic sources. Emissions from volcanoes and other natural sources constitute about 1000 tons/year. The total annual emission from anthropogenic sources is about 2500 tons, the major source being energy production from fossil fuels, especially coals with high mercury contents. Exposure to mercury vapor occurs in diminishing industrial operations, while the general population is primarily exposed to amalgam fillings.

In sediments, inorganic mercury is methylated by microorganisms to methylmercury, which is accumulated in fish. Methylmercury attains its highest concentrations in large predatory species at the top of the aquatic and marine food chains, e.g., pike, swordfish, and tuna, as well as shark, seals, and toothed whales. Increased levels of exposure have been documented in Japan, the Mediterranean region, and especially in Arctic populations. Methylmercury is readily absorbed from the gastrointestinal tract and also passes the blood–brain barrier and the placenta. In adults, the earliest symptoms are paresthesias of the fingers, the tongue, and the face, followed by problems in motor coordination. Later, tunnel vision and hearing problems occur. This syndrome was called *Minamata disease* from its appearance in a Japanese fishing village, where the local fish had been contaminated with mercury effluents from a local factory. Similar symptoms were observed in Iraq and other several countries after farmers had eaten seed grain treated with methylmercury fungicides.

Children and the fetus are more susceptible to the toxic effects of methylmercury than adults. Thus, Minamata mothers appeared in good health, but gave birth to children with a spastic paresis syndrome and severe neurological deficits. The main target organ for methylmercury toxicity is the developing brain. Epidemiological studies of prenatal exposures from maternal seafood consumption have shown more subtle neuropsychological and neurophysiological deficits that remained detectable through adolescence [3–5]. Detectable developmental delays seem to appear at maternal hair mercury concentrations of $1\text{--}3\text{ }\mu\text{g g}^{-1}$ [3] (i.e., cord blood concentrations of $4\text{--}12\text{ }\mu\text{g l}^{-1}$). In adults, the earliest clinical effects, such as paresthesias, appear to occur when blood concentrations are above $200\text{ }\mu\text{g l}^{-1}$. There is no effective antidote.

Recent epidemiological studies suggest that adverse cardiovascular effects may also occur at low-level exposures prevalent among fish consumers [6]. Although the mechanism is unknown, this evidence supports the notion that methylmercury exposure should be avoided by nonpregnant adults too.

The epidemiology evidence has inspired downward revision of methylmercury exposure limits and limits for environmental mercury releases [1, 2]. Also, governmental agencies have issued advisories regarding consumption of freshwater fish and seafood. Still, the occurrence of essential nutrients suggests that fish should be included in the diet, but maximizing the benefits would depend on the choice of fish low in mercury, i.e., smaller species, low in the food chain and from uncontaminated waters. An international agreement has been reached that mercury releases to the environment should be decreased.

The central nervous system is also the main target organ in exposures to mercury vapor. Adverse effects are well known from occupational health reports, but documented adverse effects from using amalgam fillings are apparently rare. Nonetheless, the use of amalgam in dentistry is being phased out as a preventable source of environmental mercury releases.

Meta-Analysis in Clinical Risk Assessment

Meta-analysis is a statistical approach that provides a logical structure and a quantitative methodology for the review, evaluation, and synthesis of information from independent studies. Combining the results of multiple independent studies in a well-conducted meta-analysis provides an objective summary assessment of the overall results of a series of independent studies. With the use of meta-analytic techniques, a series of clinical trials (*see* **Randomized Controlled Trials**) for example, can be summarized, and the overall treatment effect can be estimated with increased precision so that the risks of reaching incorrect conclusions from individual trials are reduced. In this article, we introduce the process of meta-analysis, issues in the conduct of a meta-analysis, and some statistical models that are commonly used to conduct a meta-analysis. The goals are to provide guidance for the interpretation of published meta-analyses as well as a framework and introduction to the tools for the conduct of a meta-analysis of clinical trials. We note that meta-analysis itself is observational in that we are summarizing experience without any experimental manipulation and deciding which studies are comparable for combinability. While meta-analyses can be conducted to summarize observational studies including case-control (*see* **Case-Control Studies**) and cohort studies (*see* **Cohort Studies**), our focus in this article is on the meta-analysis of randomized clinical trials. The material in this article is based on the paper by Friedman and Goldberg [1].

In medicine, there is a long tradition of literature review to assess the current state of knowledge with respect to the treatment of a given disease entity. The purposes of the literature review include efforts to determine the studies that have been done to address the question at hand; the results of these studies; how to compare and combine the results of the individual studies; how to interpret the results to make treatment recommendations; and what other studies need to be carried out.

The tradition of literature reviews is by its nature retrospective. When the results of published studies are inconsistent or inconclusive, it is difficult to reach a conclusion and recommendation for treatment. The inconsistencies or inconclusiveness of published

reports can result from small study sizes, varying study designs, different patient populations, varying quality of the published studies, changing technology for diagnosis and outcome measurements over time, publication bias, or the absence of negative studies in the published literature, among other reasons.

Meta-analysis methods attempt to provide a quantitative structure to address these questions. There is no one method of meta-analysis. It “is not a statistical method, *per se*, but rather an orientation toward research synthesis that uses many techniques of measurement and data analysis” [2].

The incorporation of quantitative methods into the review and synthesis of information represents an opportunity to make explicit the judgments that inevitably influence the conclusions of any summary of research in a substantive area. Many of the statistical methods used in meta-analysis predate the term, which was introduced by Glass [3]. Cochran [4] developed statistical principles for combining studies that are analogous to those for summarizing the overall results of a single study. A fundamental issue in statistics is how to assess the risk or benefit associated with the use of a new treatment. For example, how to obtain a single overall estimate of the risk of mortality in patients with a heart attack, who are treated with aspirin compared with placebo in a single randomized trial conducted in multiple centers, requires that we make several assumptions. In particular, the homogeneity of the population under study in the single trial is assumed. We can then combine the observations into a single estimate of risk and obtain its associated estimate of variability [5]. These same ideas provide a framework for meta-analysis.

In the context of using statistical methods in meta-analysis, the unit of analysis is a “study” or “trial”. Judgments are needed to decide what constitutes a study; which studies to collect; which studies to include; and then, to determine how comparable the studies are with respect to patients, design, conduct; what are the strengths and weaknesses of each study; how to define the results; what are comparable results; how to combine results; how to cope with disparity among results; and finally, how to interpret and communicate the results. Judgments about a study are made from the available reports of that study. Although there may be multiple reports of a study, no study should be included more than once in any summary. The judgments regarding the

selection of studies for inclusion and the relative importance of each study are as important as the choice of methods to combine them. The resulting meta-analysis across studies provides an increased power compared to a single trial to detect potentially important treatment effects.

Example

In 1980, six randomized multicenter clinical trials that were conducted during the 1970s, some concurrently, had been completed to evaluate the effect of aspirin compared with placebo on mortality after a heart attack. The results of these six trials are shown in Table 1 [1, 6, 7]. In contrast to each multicenter trial, there was no *a priori* plan for combining the six studies; the six studies were not planned to be conducted under a common protocol, although they overlapped in time. What could be concluded about the effects of aspirin on mortality? Was there sufficient evidence for a physician to decide to recommend aspirin for an individual patient? From a meta-analysis of these six aspirin trials, we seek to combine information to obtain a useful summary of the trial experience.

Outcome Measures

For a single study, the effect of the treatment or intervention can be measured in different ways that depend on the nature of the outcome measurement. Two treatment groups can be compared in several ways: difference between means, difference between proportions, relative risks, relative odds or odds ratios, logarithms of the odds ratio, and logarithms of the relative risks. All of these measures can be derived from the binary data for a single trial displayed as a 2×2 table. In the aspirin example shown in Table 1, the outcome variable is the total mortality rate and the treatment effect is defined as the difference between the mortality rates in the treatment and control groups. The standardized treatment effect is this difference divided by its standard error. Meta-analysts call this latter quantity the “effect size”. It is used for summaries across studies when the outcome measures are different. In the aspirin example, the outcome measures are the same for each study.

Combining Results of Studies

One of the questions to be addressed as part of a meta-analysis is can the results of the studies be combined to provide an overall estimate of treatment effect and its variability? A first step in the analysis phase of any meta-analysis is to develop and display the data to allow for a comparison of the estimated treatment effects and their associated variability from the multiple studies.

Figure 1 is an example of a commonly used graph to display this information.

Each study from Table 1 is shown with its treatment effect and associated 95% confidence limit centered at the effect (difference in mortality rates ± 2 SE). From Figure 1, we observe (a) that all of the 95% confidence limits include zero and (b) that the estimated treatment effect from AMIS is in the opposite direction. The two most commonly used methods for combining results are the simple fixed- and random-effects models. Results from these two methods, which we discuss later, are also shown. From these analyses, we note that although none of the studies were conclusive (because all of the 95% confidence limits included zero), five studies appear to favor aspirin and one does not. However, the overall result does not conclusively favor aspirin because of the dominant effect of AMIS, the largest study. In fact, without AMIS, the combined results of the remaining five studies would conclusively favor aspirin regardless of the method used to combine the information.

An alternative view of the data is to look at the relative risk of mortality rates for treatment compared with control. These estimates are also shown in Table 1. Figure 2 provides a graphical display based on the relative risks and the associated 95% confidence intervals.

Even with carefully designed protocols to conduct studies under similar guidelines, difficulties and surprises invariably occur. Centers in a single multicenter trial often are heterogeneous, complicating interpretation of the results. Indeed, in a multicenter trial, the results at the individual centers sometimes differ [5]. This problem becomes even more complex when we attempt to summarize across studies. Summary statistics, even from a single multicenter study, can be misleading when patients are heterogeneous or interactions exist among patient characteristics, treatment, and outcome. Careful attention to

Table 1 Numbers of patients and all cause mortality rates from six randomized clinical trials comparing the use of aspirin and placebo by patients after a heart attack^(a)

design and conduct issues and to operational definitions can yield insight into the interpretation of disparate results. Thus, if we are faced with these data *de novo*, we would attempt to reach some understanding of the disparity of results in these apparently similar long-term randomized clinical trials by introducing a viable framework to interpret the results and to assess the plausibility of combining the results. Our approach would be to define comparable subgroups within each study that would be predictive of outcome and to investigate the consistency of the results within strata defined by these subgroups. More specifically, the strategy would be to determine influential variables related to outcome. To do this, we would examine baseline characteristics in the different studies; effects of clinical characteristics on outcome; and patterns of interaction with treatment. Multiple methods of analysis should also be used to assess the consistency and interpretability of results.

Then we would revisit the question of which trials to combine. The ability to carry out this exercise depends on the availability of the required data in each of the publications.

A key aspect of this approach involves looking within each multicenter trial to assess the homogeneity of the centers that were combined to form the estimate of the overall treatment effect for the multicenter study. Thus, in attempts to interpret disparity among studies, we have to first look within studies to disaggregate if there is heterogeneity, and then to recombine.

Canner [6] in his overview of the six aspirin trials, carried out some adjustments for baseline characteristics among studies. Although he was unable to examine the details within studies from the published reports, he attempted to assess comparability across the studies. From his review, we note that the maximum length of patient follow-up was 12–30 months, with a minimum of 2 months except for PARIS and AMIS, where all patients were followed for 35–48 months. Thus, long-term total mortality on study may have a different meaning in the various studies. In fact, if we examine only year 1, we note that relative mortality was comparable across all six studies. A more recent meta-analysis [8] of aspirin and antiplatelet drugs that combined the results of 300 trials involving 140 000 patients has developed recommendations for subgroups of patients.

Statistical Models in Meta-Analysis

In this section, we focus on the use and interpretation of some commonly used methods of analysis that include fixed- and random-effects models.

Fixed-Effects Model

Statistical models for combining effects fall into two major classes. The simplest, or fixed-effect model, assume that there is a single “true” effect and that each study to be combined provides an unbiased estimate of this true effect. This assumption is called the *homogeneity of studies assumption*. The estimates from the individual studies may have different variability. In mathematical notation, we describe this model for N independent studies by

$$d_i = \delta + e_i \quad (1)$$

where d_i is the observed effect for the i th study and δ is the unknown true effect. The e_i is assumed to be an independent, normally distributed random variable with average value zero, no bias, and variance v_i . The variance of the i th study is estimated by s_i^2 , where s_i is the standard error of the mean treatment effect d_i in study i . For the aspirin example shown in Table 1, we see the observed values of the d_i (difference between aspirin and placebo mortality rates) and their estimated standard errors s_i . Given the fixed model assumptions, statistical theory says that the “best” estimate of the true effect is given by a weighted average of the estimated effects, where the weights are inversely proportional to the estimated variances of the d_i . In this case, the weights, w_i , are $1/s_i^2$.

Thus, the estimate of $\delta = \sum_{i=1}^6 (w_i d_i) / \sum_{i=1}^6 w_i = -0.98$ for the fixed-effect model for the aspirin example. The fixed-effect model assumptions allow for an estimate of the standard error of the estimate, which is computed as $(1 / \sum_{i=1}^6 w_i)^{1/2}$. In this instance, the standard error of the estimated true effect is 0.58 (95% confidence interval for $-0.98 \pm 1.96 (0.58) = (-2.11, 0.16)$).

Thus, the fixed-effects model-based analysis leads to a result that is consistent with no statistically significant treatment effect at the 5% level of significance because the confidence interval includes zero. If, however, we analyze only the five studies without AMIS, with the same model assumptions, we obtain an estimated overall effect of -2.47 with

standard error of 0.7567, giving 95% confidence limits of $(-3.95, -0.99)$, suggesting that aspirin usage provides a statistically significant and practical reduction on mortality at the 5% level of significance. But there was no reasonable evidence on the basis of the available knowledge at that time to assume that there was something inherently different about AMIS [6]. Table 2 provides a summary of the results of meta-analyses using the various models and different estimates of treatment effect. Notice that the fixed- and random-effects models yield identical results without AMIS, since the source of heterogeneity has been removed. We also note that year-1 mortality is significantly lower with aspirin when the six studies are combined for year 1 using this model. Therefore, the choice of endpoint as well as the choice of studies to be included can have a major effect on the conclusions of the analysis.

Estimates of the overall treatment effect measured as the relative risk from the fixed-effects model along with associated 95% confidence limits are shown in Figure 2 for total mortality. Figure 2 illustrates the results using the relative risk as the measure of treatment effect.

Tests for Homogeneity of Studies

Because the studies that are identified for inclusion in a meta-analysis are generally not designed under a common protocol, there is no *a priori* rationale for the use of the fixed-effects model with its assumption of a common treatment effect. There are statistical tests of homogeneity to examine this assumption. The Q -statistic [9] is widely used to test the null hypothesis of a common true treatment effect across all studies by a comparison of the variability within studies to the variability between studies. Failure to reject this null hypothesis because the between-study variability is not statistically significant suggests that it is plausible to combine the results of a group of studies. Rejection of the null hypothesis indicates heterogeneity among the studies and that the between-study variability must be accounted for in combining the results of the studies.

For the aspirin example, $Q = \sum_{i=1}^6 w_i (d_i - \hat{\delta})^2 = 9.57$. This statistic has a χ^2 distribution with $N - 1 = 5$ degrees of freedom under the assumption that the individual treatment effects are normally distributed with a common mean (observed $P = 0.089$). This level casts a reasonable statistical doubt on the

Table 2 Summary of meta-analysis results by model and effect measure for six randomized controlled clinical trials comparing aspirin and placebo after a heart attack

Studies available	Method of analysis	Estimate of the effect measure (95% confidence interval)		
		Difference (%)	Odds ratio	Ln odds ratio
All	Fixed effects	−0.98 (−2.12, 0.16)	0.90 (0.80, 1.02)	−0.10 (−0.23, 0.02)
	Random effects	−1.51 (−3.20, 0.19)	0.84 (0.697, 1.023)	−0.17 (−0.36, 0.02)
Without AMIS	Fixed effects	−2.47 (−3.95, −0.99)	0.76 (0.65, 0.90)	−0.27 (−0.43, −0.10)
	Random effects	−2.47 (−3.95, −0.99)	0.76 (0.65, 0.90)	−0.26 (−0.43, −0.10)
All	Bayesian fixed effects ^(a)	−0.98 (−2.14, 0.20)	0.89 (0.80, 1.0)	−0.11 (−0.24, 0.004)
	Bayesian random effects ^(a)	−1.54 (−4.12, 0.51)	0.839 (0.63, 1.05)	−0.18 (−0.458, 0.044)

^(a) Priors are $d \sim N(0, 10\,000)$ and $\sigma \sim U(0, 100)$

validity of the assumptions of the fixed-effects model because such tests of homogeneity have low statistical power. In contrast, without AMIS, $Q = 0.12$, with 4 degrees of freedom and observed significance level of $P = 0.998$. This failure to reject lends credibility to the assumption that these other five studies may be measuring a common treatment effect. However, if we include AMIS in the analysis, we need to account for the between-study variability.

Additional approaches to assess heterogeneity among studies are discussed in Higgins and Thompson [9].

Random-Effects Models

Rejection of the null hypothesis of homogeneity does not tell us whether the between-study differences are systematic or random. The random-effects model for meta-analysis assumes that the individual treatment effects are random. In the context of the aspirin example, the random-effects assumptions are that each study is estimating a different true effect, δ_i . The simple random-effects model incorporates the heterogeneity of the studies through the assumption that the studies are a random sample from a population of studies. The mean of the population of studies is the “true effect”. An estimate of the population variance is then added to the within-study variances, and a weighted average of individual study effects is

used to estimate the “true effect” in the population. In the simplest random-effects model, this population of studies has true mean effect δ , and the distribution of $\delta - \delta_i$ is assumed to be normal, mean zero, and variance τ^2 .

Thus, in this model, by assumption, between-study variability is measured by τ^2 . The effect of this model is to increase the variability associated with the d_i by τ^2 . Under this random-effects model, the overall treatment effect is estimated, as in the fixed-effects model, by a weighted average of the individual effects with weights inversely proportional to the variance of the d_i 's. In the random-effects case, the variance of the $d_i = s_i^2/\tau^2$ and the weights are $w_i^* = [1/(s_i^2 + \tau^2)]$. The overall estimate of the treatment effect is given by the same formula as above with the w_i replaced by the w_i^* . To apply this procedure, one must obtain an estimate of τ^2 . There are a number of technically complex methods to estimate τ^2 ; these methods depend on the s_i^2 , the within-study variances. We do not pursue these details here. The estimate of τ^2 attributable to DerSimonian and Laird [10] used in the following computations is 2.048 [7, 11]. Based on the w_i^* , the estimate of the overall treatment effect is −1.505 (approximate 95% confidence interval for the true treatment effect of (−3.20, 0.20)). This larger treatment effect and corresponding larger standard error is also shown in Figure 1. However, the confidence limits that result

from the random-effects model still include zero, and the conclusions of the fixed-effects model are unchanged. If we do not believe (and we do not) that these six studies are a random sample from a population of studies as required for the simple random-effects model, then we need to continue to explore the sources of heterogeneity among these studies.

Recently, Berkey *et al.* [12] proposed a random-effects regression model for meta-analysis that allows for the inclusion of other available information that may be used to explain heterogeneity among studies. If the studies are homogeneous, then both the simple random-effects model and this type of regression model reduce to the fixed-effects model. Even more complicated hierarchical models can be used with the available information to model differences among the treatment effects within studies and between studies [13].

The introduction of complications into the analysis opens up another level of judgment and decision making to ensure that statistical assumptions do not dominate the data. When there is a large disparity among effects, good measurements and expert judgments about explanatory variables are needed to provide credibility to the statistical models. The R software package is useful for the computations required for these approaches [14].

Bayesian Methods

More recently, Bayesian methods (*see Bayesian Statistics in Quantitative Risk Assessment*) that can incorporate additional information through the specification of prior distributions have become feasible for the conduct of a meta-analysis [7, 15, 16]. The development of Gibbs sampling and Markov chain Monte Carlo (MCMC) methods and the availability of software such as WinBUGS have facilitated the use of these approaches [17–19]. For the aspirin example, the results of these types of analyses with the frequentist approaches are shown in Table 2 for the different measures of treatment effect. We note that the credible intervals generated from these methods are usually wider than the corresponding confidence intervals generated from the frequentist fixed- or random-effects models.

Berry *et al.* [20] conducted a Bayesian meta-analysis to compare the dose response relationships of lipid-lowering agents that explicitly compared the

results of a study with historical data that illustrate the utility of these methods.

We note that all of the different statistical models and tests of homogeneity apply to all of the different measures of treatment effect, including the $\ln$ (relative risk) and $\ln$ (relative odds).

Other Issues in the Conduct of Meta-Analysis

Historical Perspective

There are many excellent references that review quantitative approaches to research reviews. *Summing Up* [21] is one such reference. Olkin discusses the history and goals of meta-analysis along with some examples in his introductory chapter in the Wachter and Straf publication based on a 1986 workshop [1]. The literature of meta-analysis developed along two separate paths in the social sciences and in the medical sciences. The development in the social sciences is well described in [1, 22, 23]. In the medical sciences, the 1986 Workshop on Overviews in Clinical Research was published, with discussions in *Statistics in Medicine* (1987). Many of the references cited elsewhere in this article are found in that issue, along with discussions [24–30]. In 1993, an issue of *Statistical Methods in Medical Research* devoted to meta-analysis in clinical medicine described current thinking and controversies [31–35]. The issue of *Statistical Science* devoted to meta-analysis brings together technical issues and medical and social science applications [35–40].

Statistical Methods for Combining Evidence in Studies.

The need to combine observations is ubiquitous in statistical analysis. Any time two or more observed quantities are combined into a single summary value, we are faced with a statistical problem that requires a close look at the validity of model assumptions as well as the soundness of the theoretical and philosophical basis underlying the process. The emergence of meta-analysis has fueled the interest of statisticians in combining results from different studies. This interest is reflected in the volume *Combining Information*, a publication of the National Academy of Sciences [7] that has been reissued as the first issue of *Contemporary Statistics* (vol. 1), which examines statistical issues and cross-disciplinary opportunities for research. This report

highlights the similarity of techniques in different disciplines under different names for combining information and provides an exposition of methods, free of the jargon of any one discipline, including statistics.

The published literature of meta-analyses frequently contains tests of significance of the overall treatment effect that is based on methods that we have not described. These include Fisher's method for summing the logarithms of the P values associated with each individual study, summing the P values themselves, and testing the average of the P values. Approaches such as these include each study with equal weight regardless of sample size or variability; because each study is given equal weight, these methods have fallen into disfavor [26]. Standardized treatment effects can be added using different weighting schemes to produce a weighted z -statistic as well.

Peto [28] proposes the use of the log rank statistic (or Cochran's statistic), which provides a test statistic based on summing the differences between the observed and expected numbers of events in each study weighted by their variances; this is the (O-E) method and essentially weights the $\ln$ (relative odds) by study size in a fixed-effects model framework. The Mantel-Haenszel χ^2 test [41] is also used for this same situation; the overall estimated log odds provided by this approach is preferable to the Peto estimate, unless the sample sizes in the treatment and control groups are comparable. These approaches essentially consider each study as a separate stratum in the fixed-effect model framework. Fleiss [33] and DeMets [26], among others, provide careful expositions of these methods and their application.

Other reviews of statistical approaches for combining similar experiments can be found in Hedges and Olkin [22], Whitehead and Whitehead [42], Goodman [43], Zucker and Yusuf [44], and Berlin *et al.* [45], who, among others, discuss alternative methods of meta-analysis. A critical review of the use and application of meta-analytical results may be found in Thompson and Pocock [46] and Boden [47]. Mann [48] reviews the diversity of applications of meta-analysis. A more recent review and exposition of methods can be found in the volume edited by Cooper and Hedges [23].

The book by Bryk and Raudenbush [13] provides a good introduction to some of the more sophisticated modeling techniques that we just discussed.

This type of hierarchical modeling will become more prevalent in meta-analysis as the view of Rubin [49] becomes more accepted. He makes the distinction between meta-analysis for "literature synthesis" and meta-analysis for "understanding the science". In the former, the concern is with sampling from the finite population of studies that have been done and summarizing the results of these studies by some average effect with some appropriate weighting, as in the fixed-effects approaches we described previously.

The references provided in the body of this paper provide further examples of the attempt to use statistical methods to aid in the understanding of disparate results.

Guidelines for Planning and Carrying out Meta-Analysis

To successfully carry out a meta-analysis, the techniques of statistical analysis must be integrated with the subject matter. To accomplish this task, expert medical knowledge of the subject matter must be brought to bear on the key decision points in the process. There is no theory or formalism to direct the process of carrying out a meta-analysis. At best, there are informal guidelines for the practice of meta-analysis. These informal guidelines are best understood in the context of case studies.

The best opportunity for carrying out a successful meta-analysis would arise from the prospective planning of a sequence of studies for combinability along the lines of a multicenter trial. Short of prospective planning, standards within subject matter areas for the reporting primary results of clinical studies need to be developed. Suggestions along these lines have been made by Mosteller [50]. Other useful sources of guidelines for the conduct of meta-analyses include Wachter and Straf [2] and Cooper and Hedges [23]. These issues address the identification of studies for inclusion in the meta-analysis, retrieval techniques, selection of studies, quality of studies, and analysis. The Cochrane Collaboration [51] is a major source of guidance for the conduct of meta-analyses or overviews and is a repository for overviews based on the patient level data from clinical trials in a variety of areas of medicine.

Issues in Meta-Analyses in Medicine

Most of the issues that were identified in the publication of the 1986 Workshop on Methodologic Issues

in Clinical Trials [6, 24–30] are still being debated. The issue of *Statistical Methods in Medical Research* in 1993 [31–35] was devoted to these same issues. These issues, critical to the conduct and interpretation of a meta-analysis, include publication bias or study selection problems, assessment of study and data quality, criteria for inclusion and exclusion of studies in the meta-analysis, statistical methods for combining, and the interpretation and generalizability of the results. The collection of “all” studies is difficult and time consuming [23], and involves identification and assembly of published and unpublished literature identified through indices, Medline, registries, and files. Further, many studies appear in several different published formats, as abstracts, as proceedings, as interim reports, and as final reports. Because the assumption in the applicable statistical methods requires that studies be independent, only one report of any study should be included – the final report.

The opposite problem to be faced is “what else is there”; i.e., what studies have not been published? What is the effect of publication bias on the results of a meta-analysis? Negative studies are not as likely as positive studies to be published; are there enough such studies to change the results of a meta-analysis of published literature? The “file-drawer problem” has been addressed by several investigators who have developed methods to estimate the number of negative studies [22, 52]. Other approaches include methods of weighting in the analysis [22, 36–38].

The issue of which studies to include requires that criteria be developed. The decisions to consider here are whether to restrict the analysis only to randomized, controlled trials or to include other kinds of studies. We restricted ourselves to randomized, controlled trials for the reasons discussed earlier. Even with this restriction, many decisions need to be made explicit. Study design, treatment regimens, control regimens, patient inclusion and exclusion criteria, study size, duration of patient observation, outcome assessments, and study quality need to be explicitly documented and discussed. Chalmers *et al.* [24] and Sacks *et al.* [53, 54] recommend dual, blinded abstraction and review, including quality assessments of studies, to develop the databases for analysis. Alternatively, however, one can consider the equivalent of the “intent-to-treat” notion in the reporting of results of individual randomized clinical

trials. In the context of clinical trials, intent-to-treat refers to the notion that all randomized patients are included in the analysis; that is, there are no *post hoc* exclusions. An intent-to-treat design for a clinical trial requires detailed *a priori* operational definitions to enable inclusion and exclusion criteria before randomization to be consistently applied by all investigators. The spirit of this view would lead to the inclusion of almost all identified randomized trials. This is consistent with the views of Peto [28], who suggests minimal exclusion criteria and eliminates many of the so-called objective judgments that are themselves subjective. Quality and other aspects of the studies can be addressed in the process of meta-analysis by the use of sensitivity analysis to assess the impact of any questionable studies on the results of the meta-analysis. For example, the effects of the inclusion of abstracts can also be assessed in this way. Sensitivity analysis would consist of the recomputation of estimated treatment effects with the study or studies in question removed and examination of the influence of the removed observations on the results and conclusions.

Others go beyond the selection of studies for inclusion to suggest guidelines for the inclusion of patient data within studies. This approach requires that data from individual patients or subgroups of patients be obtained. The meta-analysis is then based on the individual data within studies in the analysis [25, 28, 51]. The purpose of such an exercise is to put all of the data from multiple sources into a single database with common conventions and procedures surrounding the processing of the information. This is, of course, only possible to the extent that the procedures and measurements in the trials are similar. The opportunities available to the researcher who obtains such data are presented in our discussion of the aspirin data.

Why Meta-Analysis?

The purpose of meta-analysis is itself a source of controversy. Mosteller and Chalmers [39], Antman *et al.* [11], and Chalmers and Lau [35] have proposed that small, inconclusive studies can be combined in an ongoing manner so that large trials may be avoided if the accumulating evidence from small trials becomes conclusive. That is, before a new large study is undertaken, prior evidence should be evaluated. Peto [28] proposes meta-analysis primarily to

assess the presence of moderately small effects on endpoints such as mortality, essentially in lieu of large, simple trials. He and his colleagues also argue that individual patient data should be included in meta-analyses or overviews to enable common operational definitions to be used. Such large, simple trials have minimal entry criteria and data collection requirements, and are closest to an overview in spirit in that the results obtained are average results over large, possibly heterogeneous patient groups.

Concluding Remarks

The concerns of meta-analysis touch on fundamental issues in science, including what is evidence; how does it accumulate; and how do we learn from experience? The statistical methods applicable to meta-analysis are evolving and becoming more complex; information in speciality areas of medicine is growing rapidly. Many of the issues that we have raised in this article are still being debated. While this debate continues, any report of a meta-analysis should make explicit all judgments regarding the issues that we identified in the earlier section on guidelines for planning and carrying out a meta-analysis. A meta-analysis should include the peer-reviewed published reports of all identified randomized studies only once. This is the primary meta-analysis. If any other types of reports or abstracts of studies of any type are included in the review, the results should be reported separately for the various types of reports to enable the reader to assess the possible effects on the conclusions of the primary meta-analysis. All other judgments and descriptions of analysis should also be made explicit, and adequate information should be provided to allow the reader to make his or her own judgments.

There is a serious requirement to plan for meta-analysis in a manner analogous to the multicenter clinical trial model. Furthermore, one should not underestimate the inherent difficulties in searching for studies and in finding useful information in the studies. We recommend that the process of meta-analysis be carried out collaboratively between subject matter experts and statisticians.

Although meta-analysis is often said to increase power to detect a statistically significant treatment

effect, such an exercise can be misleading if the judgments concerning combinability are incorrect that is, if the studies included are seriously flawed or heterogeneous. Real disparity among studies is not resolved by statistical models alone. Model assumptions are not an adequate substitute for the detective work required to uncover the causes of disparity. Furthermore, the sensitivity and robustness of the results to judgments about the subject matter and to statistical assumptions should be analyzed and reported. Although we have shown that different methods of analysis can give rise to some differences in the results of a meta-analysis (and its interpretation), the choices made by the meta-analyst with respect to all of the issues that we have discussed can dominate any analysis.

As Mosteller [50] points out, a meta-analysis still may be considered successful if one can document that the available information is inadequate to answer the question at hand. In such a case, if the question is important enough, a well-designed and well-conducted primary research study should be performed.

In the process of summarizing overall results and treatment effects, one should be careful not to overlook the anomalies that have been uncovered in the process. These anomalies may be very real contributions to the subject area.

Meta-Analysis in Nonclinical Risk Assessment

Background

Systematic review and meta-analysis methods are widely used to summarize and combine results of clinical trials (*see* **Randomized Controlled Trials**), forming the basis for evidence-based medicine [1]. They are also increasingly popular in epidemiology, but they remain relatively rare in toxicology despite some early signs of their uptake there [2, 3]. They have been used for some time in disciplines other than health research, such as education and psychology. Increasing adoption of such techniques reflects the emphasis on “evidence-based” approaches, as well as explosion of publication rates of primary studies beyond the capacity of many researchers. Systematic reviews use explicit, transparent, repeatable criteria to identify, review, and evaluate evidence while seeking to minimize possible biases [4, 5] in identifying, evaluating, and summarizing all the available and relevant evidence concerning a clearly focused, predefined research question. Where appropriate, systematic reviews can be extended into meta-analyses: the quantitative synthesis of results from individual studies.

Systematic reviews and meta-analyses have the potential to help improve the objectivity and transparency of the current risk assessment process through contribution to several aspects of risk assessment, principally in the risk estimation phase. Potentially, they can contribute whenever more than one estimate of a parameter in a risk assessment or decision analysis model (*see* **Multiaattribute Utility Functions**) is available, provided these estimates can legitimately be combined. They will most obviously be useful in summarizing evidence on exposure–disease relationships, from animal toxicology experiments (*see* **Cancer Risk Evaluation from Animal Studies**) or from epidemiological studies in humans, or perhaps at a later stage in combining these two (and potentially other) types of evidence.

Use of systematic criteria force the process to be more systematic, thus allowing readers and users of systematic reviews to have a better understanding of

the results and recommendations given the assumptions and decisions made in the review process [6]. Advantages of using systematic review methods to review and summarize evidence are well documented in several health and related research fields [4, 5, 7, 8]. In a systematic review (but not necessarily in a traditional or narrative review), the target research question; methods used to identify, obtain and select relevant evidence of an appropriate quality; and the results obtained, including any assumptions and judgments made in synthesizing primary data are set out in a standardized and explicit way [4, 5]. This provides transparency of methodology, allows reproducibility, and facilitates updating as new evidence becomes available. Deficiencies in the existing literature may be highlighted, so future research priorities can be identified.

Quantitative synthesis of results from several studies (meta-analysis) may be advantageous and appropriate. Meta-analyses offer greater statistical power and more precise estimates than the primary studies, if it is appropriate to combine the results of a set of studies investigating a common intervention, exposure, or feature. They also provide a framework for investigation of sources of heterogeneity; combining several sources of evidence, derived from a number of studies possibly with differing designs, for example, may increase the generalizability of the results, and allow a full exploration of the effects in subgroups. In the broad risk assessment context, extensions of the standard meta-analytical techniques into comprehensive decision modeling approaches begin to merge with probabilistic risk assessment modeling approaches (*see* **Comparative Risk Assessment**).

Areas of application thus include risk assessment procedures for setting standards for human exposure to environmental pollutants (*see* **Environmental Hazard**) and safety testing and dose establishment in development of therapeutic drugs. In these fields, review and combination of evidence often rely on expert but informal methods, but sometimes on quantitative methods based on biomathematical models. Assumptions and judgments are implicit throughout, whichever approach is adopted, but are typically more transparent when systematic review and meta-analysis, or other explicit modeling approaches, are employed. Transparency regarding the various assumptions made, and identification and quantification of uncertainty in the resultant exposure limit estimates are essential for those involved in the review

process and for professional users and “consumers” of the results alike.

Outline of Systematic Review and Meta-Analysis Methods

There are a number of important steps in any systematic review, and these are described and discussed in the procedural documentation from the Cochrane Collaboration [1] and the Centre for Reviews and Dissemination [9]. The steps include

1. formulating the research question to be addressed in the systematic review/meta-analysis;
2. development of an explicit protocol for the systematic review/meta-analysis;
3. identifying and selecting primary studies to be included in the systematic review/meta-analysis;
4. assessing the quality of the primary studies;
5. extraction of the results of the primary studies;
6. synthesis (if appropriate) of primary study results through meta-analysis;
7. interpreting results of systematic reviews/meta-analyses and formulating recommendations based on them.

These aspects of a systematic review are important regardless of the area of application. Several sets of guidelines on the review process have been available for some time for the combination of randomized controlled trials [1, 9]; for epidemiological studies [10, 11], where meta-analysis often needs to be used in an exploratory rather than definitive analysis mode because of the dangers of bias in primary studies [12]; and latterly for animal toxicology experiments [3, 13]. Methodology for systematic reviews encompasses many topics, from prereview issues, such as methods of literature searching, through mainstream methods of description and synthesis, to the dissemination of the reviews findings. A brief resumé of some of the principal statistical methods available for formally combining several study estimates is given below. Methods specific to various outcome measures and data types are also available, and are described elsewhere [4, 5].

Search Methods

The procedural methodology for all stages of a systematic review has been clearly defined in two sets of

guidelines [1, 9]. A study protocol should be drawn up to establish the procedures used *before* a review is undertaken to avoid bias due to decisions made when the results of the review are known. Multiple methods [14], usually (multiple) electronic database searching complemented by handsearching of key journals by “explosion” of relevant entries in the reference lists of articles identified, are needed. Searches must be documented sufficiently to allow others to replicate them, and in due course update them. After the potentially relevant study reports have been identified, their relevance for inclusion in the systematic review/meta-analysis must be assessed. (For example, have they been performed in circumstances or contexts that allow their results to be regarded as valid in the target situation?) Not surprisingly, the results of systematic reviews may be sensitive to methods of searching and subsequent inclusion criteria [15].

Study Quality Assessment

It is common to assess the quality of the primary studies eligible for inclusion in the review. Exclusion of poor quality studies, or at least a downweighting of them in a formal pooled analysis, may appear sensible, but in fact there is little consensus on the most appropriate strategy. Although scales for scoring study quality exist for some study types [16], the validity of these instruments is not established [17], and guidelines for even the reporting of observational studies lag behind those for clinical trials [18]. Exploration of the influence of components of study design and conduct associated with study quality may be more appropriate. Sensitivity analysis of the impact on the subsequent decisions made concerning quality and of pooled estimates obtained as a result is essential; typically this sensitivity analysis will entail repeating the analysis on subsets of the data meeting increasingly stringent quality criteria.

Meta-Analysis and Evidence Synthesis

As indicated in step 6 above, in some cases a systematic review may be extended to a meta-analysis, allowing quantitative estimation of effects across similar studies. Whether this is advisable and justifiable will depend on the combinability of the results from the individual primary studies – for example, are they measuring similar outcomes or will it be a case of combining “apples and oranges”

[19] – and on the impact of potential problems including publication bias discussed below.

The most commonly reported pooled estimate is calculated as a weighted average of the results of primary studies, the weight given to each study depending on the precision of the estimate from it, so that studies with large precision are given more weight in the meta-analysis [4]. Other methods such as vote counting (tallying “positive” and “negative” studies relating to a particular issue) or combination of p values of effects in each study are occasionally necessary owing to limitations in information available from study reports, but neither method yields a pooled estimate of effect size [20]. Methods that do provide a pooled estimate of effect size are generally known as *inverse-variance weighted* meta-analysis models.

Heterogeneity

The variability in the true underlying effects between studies in a meta-analysis [21], known as *between-study heterogeneity*, is an important feature of any meta-analysis that must be considered and explored. Failure to allow for such heterogeneity may lead to inappropriate results. If heterogeneity is “substantial”, for example, as assessed with the I^2 criterion (the proportion of total variation in study estimates that is due to heterogeneity [21]), combining study estimates may make little sense; more generally, if present, heterogeneity should be accounted for as far as possible in the analysis, in terms of sources such as different populations or contexts studied in the primary studies, differing primary study methodologies, varying endpoint definitions, and study quality markers. Generally, no consensus has been reached concerning the best strategy for dealing with heterogeneity, although the use of mixed modeling section titled “Meta-Regression and Mixed Models”, is recommended.

Fixed Effect Models

Fixed and random-effects models are commonly used in meta-analysis and choice of one over the other depends on the variability of the study-specific estimates assumed within the meta-analysis. The fixed effect method assumes all the studies are estimating the same, underlying treatment effect, and hence that no heterogeneity is present, which is often unrealistic. For continuous outcome measures

a weighted average of the primary study estimates (on a standardized scale) is calculated, giving a weighting to each that is proportional to the inverse of its variance. Several estimation methods have been proposed when the outcome is an odds ratio [22] as it often will be in risk assessment contexts. Although the results of the different methods will often be similar, in some circumstances serious differences can arise [23].

Random Effect Models

A random effect model [24], which can incorporate some aspects of heterogeneity when pooling estimates, is a popular alternative to the fixed effect method. Such models assume that the true effect size values for each study are not identical, but are drawn from an underlying distribution (usually assumed to be a normal distribution) of effect sizes on an appropriate scale, and that it is the mean of this distribution that is of interest. As a result of incorporating extra variation (due to heterogeneity present between studies), the confidence interval obtained for the pooled estimate is wider than that of the fixed effect method, so it is more conservative. The point estimate may also differ, as this method reduces the weighting of the larger studies and increases the relative weight given to the smaller studies, compared to the fixed effect model. These points are illustrated in the forest plots in Figure 1, which show dose–response estimates from primary studies of exposure to trihalomethanes and low birth weight with within-discipline fixed and random-effects meta-analysis estimates, which were subsequently synthesized using more complex models [25]. The uncertainty involved in estimating the between-study variance needs to be incorporated as well [26]; this widens the resulting confidence interval further. Random effects models have been criticized on grounds that unrealistic or unjustified distributional assumptions may have to be made in implementing them [27]. Neither fixed nor random effect analysis can be considered ideal, and the choice between them remains a source of controversy [28]. As noted below, combination of evidence of diverse types in risk assessment may in any case require *generalized synthesis of evidence* methods, extending conventional meta-analysis techniques.

^a The details of all the references cited in this figure are available in [25].

Figure 1 Study-specific dose-response estimates and 95% confidence intervals, with fixed and random effects meta-analysis estimates and 95% confidence intervals

Meta-Regression and Mixed Models

Although random effect models allow for between-study heterogeneity, if all or part of this variation is systematic, it may be possible to extend the model to include variables that explain it. Such analyses should usually be treated as exploratory, since associations between characteristics and the outcome can occur purely by chance or may be due to the presence of confounding factors. If study level covariates are included in fixed and random effect models, meta-regression and mixed models, respectively, result [29]. The mixed-modeling approach may be recommended in instances where covariates explain part of the heterogeneity, but a random effect term is required to “accommodate” the remainder [30].

Publication and Related Biases

Publication biases arise because statistically significant, interesting or “welcome” results are potentially more likely to be submitted, published or published quickly, and published in English. There is no consensus [31] on how best to proceed when publication bias is suspected, and methodological research in this area is active at present. “Funnel” plots of some measure of sample size *versus* effect size are often inspected for asymmetry, which may arise as a result of publication bias, but may also been seen for other reasons [32]. More formal tests or investigations are also performed [33, 34]. Even if a study is published, selection biases may operate in respect of the particular endpoints and covariate effects reported [35]. This is arguably more likely

in observational epidemiological studies than when the primary studies are experimental, and perhaps also in risk assessment contexts in which government, non-governmental agency, and industry data are not always published or made widely available.

Using Data on Individual Subjects

An alternative approach to combining aggregated study results is to gather individual subject data from the study investigators (if they are willing to provide it), and carry out a meta-analysis on data at the individual subject or animal level [36]. This is particularly useful for the synthesis of certain types of study designs such as survival or repeated measures studies, and allows detailed data checking, and the appropriateness of the analyses to be ensured. Such individual subject level meta-analyses are, however, usually both very time consuming and costly, so they are comparatively rarely carried out [37].

Applications of Systematic Review and Meta-Analysis in Risk Assessment

Methods for human health risk assessment of environmental exposures (*see **Environmental Health Risk Assessment***) are frequently based on conventional narrative reviews of usually diverse evidence (including both human and animal data). When limits for human exposure to these chemicals need to be determined, the limits may be based on the results from animal experiments, the dose level observed to cause no or little adverse effects in animals being divided by a number of safety or uncertainty factors in obtaining a limit for human exposure [38, 39]. More complex models based on biological processes are also used in risk assessment [40] but may require evidence that is rarely available. Thus current strategies for reviewing and incorporating evidence in risk assessments are often not systematic and transparent (with the prevalence results in the gray – not formally published – literature being a special problem in this area), and may lack some degree of quantification [41]. The nature and degree of uncertainty that exist in the estimation of these exposure limits need to be clear to both setters and users of the limits.

A review of a number of comparable risk assessments (of lung cancer and exposure to chromium

(*see **Hexavalent Chromium***)) comments that different risk assessments often result in different exposure levels being recommended because of differences in the evidence base, the methods used, and the assumptions made, the basis for which is not always clear [41]. For example, if a choice of pivotal study has been made, it may well be important to ask how sensitive the conclusions of the risk assessment are to that choice. Further, use of just one study as the basis for calculation (of an exposure limit, for example) may be inefficient when there is evidence also available from other relevant studies.

Examples of Systematic Review and Meta-Analysis in Risk Assessment

Although the use of meta-analysis in risk assessment was considered some time ago [42], adoption of the technique has been limited to date. Examples of use of systematic review and meta-analysis methods in risk assessment contexts include a meta-analysis of epidemiological evidence in a risk assessment of dimethoate [43], modeling outcome severity in terms of tetrachloroethylene exposure concentrations and durations and other covariates [44], and synthesis of evidence from more than one species exposed to hydrogen sulfide [45].

Other approaches relevant to the quantitative synthesis of evidence for a risk assessment have been developed. These methods include hierarchical Bayesian models for combination of evidence (on dose–response relationships) in several species [25] related to generalized synthesis methods considered below, direct modeling of the relevance of cross-species evidence in a Bayesian framework [46], and other modeling approaches [47]. Bayesian hierarchical models have also been used to combine estimates of potency from mutagenesis arrays of toxic environmental agents [48].

However, although examples of use of meta-analytic techniques can be found, there is little evidence to date of the widespread use of systematic review methods in the risk assessment process even though it could be argued that systematic review methods are more important than, or at least more widely applicable than, the quantitative synthesis. Further, meta-analyses not preceded by systematic review are in danger of providing quantitative estimate of risk, with associated levels of uncertainty, on the basis of incomplete data sets, with problems

analogous to those arising from publication bias (in which study reports would not be found even if a search had been performed).

We now consider in turn some characteristic features of applications of systematic review, meta-analysis, and related approaches in contexts characteristic of risk assessment. In particular, use of the techniques to summarize the results of *animal experiments* is in its infancy. When the studies to be summarized and combined are *observational*, as in the case of epidemiological studies, some further considerations arise from the potential for bias in such studies. Most risk assessments will require combination of evidence of diverse types or from diverse study types – for example, data on dose–response relationships from animal toxicology experiments and from observational epidemiological studies in humans. This may require *generalized synthesis of evidence* methods, extending conventional meta-analysis techniques, and often using *Bayesian methods*; in turn these may be developed into *comprehensive decision models* [49].

Animal Studies

Despite calls to make the risk assessment process more systematic and transparent [41, 50], the uptake for review and summary of animal experiments is still low [3, 13], with a few notable exceptions including articles in the radiation biology field [51] and on the genotoxicity of pesticides [52] demonstrating explicit description and specification of literature search terms and procedures, and of inclusion and exclusion criteria. Furthermore there is considerable room for improvement in the quality of systematic reviews and meta-analyses of animal experiments [3, 13].

Observational Epidemiological Studies

Since observational studies, including almost all epidemiological studies of the risks of disease associated with exposure in humans, are prone to a greater range and potential degree of bias than good experimental studies (toxicological experiments in animals or randomized clinical trials in humans), caution is needed in combining their results in meta-analyses [53]. Otherwise misleading precision may be achieved through pooling of primary studies suffering from substantial (and varied) biases, so that including

studies with poor designs may weaken the analysis by increasing bias [12, 54, 55]. This issue may be partially addressed by conducting sensitivity analyses under various credibility assumptions [56]. A set of guidelines for meta-analysis applied to environmental health issues [10] is more broadly applicable to observational studies in other similar areas and another report considers meta-analysis of epidemiological studies in risk assessment [57].

Generalized Synthesis of Evidence and Bayesian Methods

The Confidence Profile approach [58] was a forerunner to other cross-design synthesis methods [59], which allowed adjustments in the analysis to be made in principle for different study characteristics and biases. Development of synthesis approaches incorporating direct modeling of biases is currently an active area of research [60]. Methods for combination of studies with disparate designs into a single synthesis have often used Bayesian hierarchical modeling approaches [25, 61]. The hierarchical nature of the model specifically allows quantitatively, for both within and between design sources of heterogeneity, whilst the Bayesian approach can accommodate *a priori* beliefs regarding qualitative differences between the various sources of evidence, and levels of between-study heterogeneity [62]. Prior distributions may represent subjective beliefs elicited from experts (with explicit acknowledgement that different individuals may hold different *a priori* beliefs), or other data-based evidence, which though pertinent to the issue in question is not of a form that can be directly incorporated. This model can be viewed as an extension of the standard random-effects model described above, but with an extra level of variation to allow for variability in effect sizes between different sources. Bayesian approaches also allow probability statements to be made directly regarding quantities of interest, and predictive statements to be made, conditional on the current state of knowledge. They lead naturally into a decision analysis framework, which can also take into account utilities when making health care or policy decisions [63] and underlie many probabilistic risk assessment models [64].

Conclusions

Systematic review and meta-analysis methods have useful contributions to make to current risk assessment approaches. The use of systematic review methods means that clear criteria for searching for and identification of relevant studies can be defined and reported, allowing ease in updating and repeating the search process. These methods also provide a structured and systematic approach to the review of diverse human and animal evidence, maximizing efficient use of already available evidence [65], and facilitating identification of “gaps” in the knowledge base – perhaps that more epidemiological studies are needed to help answer the question of interest – the strategy for filling which could potentially be formalized by application of value-of-information methods [66].

Using meta-analysis methods in risk assessment means that *quantitative* summaries of evidence can be obtained, making it possible to estimate the amount by which risk is increased in those exposed to the substance compared to those not exposed, for example, rather than just being able to say that evidence of an increase in risk exists. A meta-analytical framework allows investigation of between-study heterogeneity and of publication bias, which may in turn provide information and insights not obtainable through reliance on just one (pivotal) study, and which facilitates sensitivity analyses [56] to help assess the impact of assumptions made in the procedures. In meta-analysis of observational studies in particular, where a variety of biases, some unrecognized or unmeasured, may operate in the primary studies, meta-analysis can prove to be an invaluable exploratory tool. The potential increase in power of a meta-analysis compared to that of an individual study makes it especially appealing for animal toxicology experiments where it may help in pursuing the 3Rs of animal research [67] by *reducing* the number of animals used, since data from individual studies are efficiently combined. An understanding of sources of bias in the individual studies may result from a meta-analysis and lead to improvements in the quality of conducting and reporting human studies and animal experiments [68]. More generally, incorporation of meta-analytical results into comprehensive decision models represents a valuable direction of development of probabilistic risk assessment modeling approaches.

Methylmercury

Biogeochemistry

Mercury (Hg) is a heavy metal that is dispersed into the environment as a result of both natural processes and human activities. The natural sources include volcanic emissions, the weathering of rock containing Hg ore, and undersea vents. The major human-related (anthropogenic) pathway of exposure is the combustion of carbon-based fuels, particularly by coal-fired power plants. The use of Hg as an amalgamator in gold mining operations has resulted in contamination in certain locales. Other anthropogenic pathways include municipal, medical, and hazardous waste incineration, although, in the United States, the importance of these pathways has diminished as a result of more stringent regulations regarding the amount of Hg allowed in the waste stream. Because of the complex biogeochemistry of Hg fate and long-range transport in the atmosphere [1], it is difficult to quantify the relative contributions of these different sources and pathways to global Hg pollution. However, anthropogenic processes are thought to be responsible for at least 50% of the total yearly dispersion of Hg into the environment [2–4].

Hg is present in the environment in metallic, inorganic, and organic forms. Interconversion between forms can occur. Great attention has been paid in recent years to human exposures to one particular organic form, methylmercury (MeHg). The primary route of human exposure to MeHg is the consumption of food substances taken from contaminated water (see **Water Pollution Risk**). MeHg results when elemental and inorganic Hg deposited in waterbodies is biotransformed through the process of methylation by phytoplanktons (marine environments) and sulfate-reducing bacteria in anoxic or suboxic sediments and waters (freshwater environments) [5]. In heterotrophic organisms, MeHg bioaccumulates and biomagnifies as it ascends the aquatic food chain. As a result, the greatest tissue concentrations are generally found in animals at the highest trophic levels, i.e., long-lived predatory species. In the marine environment, these include certain sharks, whales, swordfish, and tuna. In the freshwater environment, they include bass, pike, walleye, and pickerel. MeHg levels can also be high in animals that feed on marine life, such as polar bears, otters, mink, and piscivorous

birds (e.g., loons, eagles, osprey, ducks, herons, and kingfishers).

Toxicokinetics

MeHg is not lipophilic (fat soluble). Therefore, it is present in the largest concentrations in muscle tissues rather than in fat or oil. MeHg concentrations are unaffected by preparation or cooking methods. Because of biomagnification, the concentration of MeHg in fish tissues can be orders of magnitude greater than the concentration of Hg in surrounding water. Approximately 95% of ingested MeHg is absorbed from the gastrointestinal tract. The half-life of MeHg in blood in humans is estimated to be 50 days, and the whole-body half-life to be 70–80 days. The residence time of Hg in the brain, into which MeHg is actively transported on the large neutral amino acid carrier [6], however, appears to be considerably longer [7]. The primary route of excretion of MeHg is by means of demethylation by organisms in the gut and excretion of the resulting inorganic form in feces. Another route of elimination is hair. The Hg concentration in hair is approximately 250 times greater than the concentration in blood, although this ratio can vary widely depending on level of exposure, age, and other factors [8]. Because at least 80% of the Hg in hair is in the form of MeHg, total hair Hg is frequently used in epidemiological studies as an exposure biomarker for MeHg, and is particularly useful in studies of populations of high fish consumers. MeHg is actively transported across the placenta [9] and maternal hair Hg level at delivery correlates reasonably well with the level of Hg in the infant brain ($r = 0.6–0.8$, depending on brain region) [10].

Human Health Effects

The devastating effects of high-dose exposures to MeHg on human health were first recognized following the decades-long poisoning that occurred in the population living near Minamata Bay in southern Japan as a result of industrial discharge of effluent containing methylmercury chloride. Women who consumed MeHg-contaminated fish gave birth to children who suffered from what came to be called *congenital Minamata disease (CMD)*. The signs of CMD included growth disturbances, primitive reflexes,

movement and coordination disorders (cerebellar ataxia, chorea, athetosis, and dysarthria), sensory impairments, cerebral palsy, and mental retardation. Because of the delay in identifying MeHg as the cause, the critical MeHg dose required to cause CMD could not be determined with certainty. Other episodes of mass poisoning were recognized in Niigata, Japan, in the 1960s, and in Iraq in the 1970s. In the latter episode, seed grain treated with a fungicide containing MeHg was consumed rather than planted. The adverse effects in children who were exposed to MeHg prenatally were similar to those observed in Minamata. In both the Japanese and Iraqi episodes, it was noted anecdotally that mothers of many affected children were asymptomatic or suffered only mild difficulties such as transient paresthesias, particularly in the extremities and perioral region. This observation suggested that pregnant women are the critical population subgroup with regard to MeHg exposure. In its 1990 risk assessment, the World Health Organization (WHO) identified the Iraqi episode as the critical study and concluded that, "A prudent interpretation . . . implies that a 5% risk (of developmental delay in offspring) may be associated with a peak Hg level of 10–20 ppm (parts per million) in the maternal hair" [11, p. 103].

Examination of the pathological changes in the brains of individuals poisoned with MeHg toxicity in the Minamata episode provided clues to the explanation for the greater sensitivity of the fetal nervous system, compared with the adult nervous system. A striking age dependence was noted in the distribution of lesions in the brain. The injuries were highly focal in individuals who were exposed only as adults and were located primarily in the cerebellum (particularly granule cells), the calcarine fissure of the occipital cortex, and pre- and post-central gyrus. This pattern accords well with the typical clinical signs of adult MeHg poisoning, which include distal sensory disturbances, constriction of visual fields, dysarthria, tremor, and ataxia. In contrast, lesions were diffusely distributed throughout the brain [12] among individuals exposed prenatally. This is because MeHg disrupts neuronal cell proliferation and migration, resulting in structural abnormalities that include reduced cell densities, islands of heterotopic neurons (i.e., incorrectly located), glial proliferation, incomplete myelination, and disturbances in brain cytoarchitecture. Among the possible mechanisms of MeHg neurotoxicity are disorganization

of the microtubular system, oxidative stress injury, mitochondrial dysfunction, and inhibition in protein and macromolecular synthesis [13].

Recognizing the devastating effects of high-dose exposure to MeHg on the fetus, investigators were led, beginning in the 1980s, to ask whether milder neurological effects were associated with the lower in utero exposures to MeHg that are more typical within the general population of seafood consumers. To evaluate this hypothesis, several longitudinal prospective studies were undertaken in populations of frequent fish consumers. The most important of these studies were conducted in New Zealand, the Faroe Islands (located in the Northern Atlantic Ocean), and the Seychelles Islands (located in the western Indian Ocean). The women enrolled in the Seychelles Islands study, for example, reported eating an average of 12 "fish meals" per week [14]. Approximately half of the Faroese women consumed "fish dinners" three or more times per week, and 80% consumed one or more "pilot whale dinners" per month [15]. The New Zealand and Faroe Islands studies have generally been interpreted as demonstrating inverse associations between subclinical prenatal exposure to MeHg and children's neurodevelopment. In the Faroes Islands study, cord-blood Hg level was inversely associated with children's neuropsychological test scores at ages 7 and 14 years [16, 17]. In addition, higher Hg levels in children's hair at 14 years of age were associated with delayed responses on brain stem auditory evoked potentials [18]. In the New Zealand study, maternal hair Hg level greater than 10 ppm was associated with a doubling of the risk that a child would have an IQ score below 70 [19]. The Seychelles Islands study has generally been interpreted as providing little evidence of adverse effects from higher MeHg exposures [20, 21].

Approaches to Risk Assessment

The apparent discrepancies in the findings of the New Zealand, Seychelles Islands, and Faroe Islands studies have posed challenges to risk assessors attempting to establish intake limits for MeHg, and considerable effort has been invested in the search for possible explanations [7]. Recent integrative analyses suggest that although the findings of the three studies appear to differ if compared solely on the basis of *P* values associated with the dose–effect relationships (*see*

Dose–Response Analysis), the inverse slopes of the relationships are actually quite similar across studies [22]. Nevertheless, different regulatory agencies have made different choices regarding the critical study. The US Environmental Protection Agency (US EPA) relied primarily on the Faroe Islands study in deriving its RfD of $0.1 \mu\text{g Hg/kg body weight/day}$, although the findings of the New Zealand study and, to a lesser extent, the Seychelles Islands study provided supporting evidence [23]. The US Agency for Toxic Substances and Disease Registry used the Seychelles Islands study to derive its minimal risk level of $0.3 \mu\text{g Hg/kg body weight/day}$, expressing concern that some of the apparent adverse effects attributed to MeHg in the Faroe Islands study might be the result of residual confounding by coexposures to persistent organic contaminants present in pilot whale blubber [24]. The Joint Expert Committee on Food Additives and Contaminants (JECFA), a committee of the WHO and the Food and Agriculture Organization, did not consider the New Zealand study in its risk assessment because of concerns about the inordinate influence on the results of one observation, a maternal hair Hg level of 86 ppm, which was more than four times higher than the next highest concentration in this study sample. Therefore, the JECFA derived the provisional tolerable weekly intake of $1.6 \mu\text{g Hg/kg body weight/week}$ (or $0.23 \mu\text{g Hg/kg body weight/day}$) on the basis of the Faroes Islands and Seychelles Islands studies [25]. Another factor contributing to the discrepancies among the intake limits derived by regulatory groups is differences in the underlying assumptions, most notably in the uncertainty factors applied.

To illustrate a MeHg risk assessment, the approach used by the US EPA to derive the RfD is described. The RfD is defined as, "... an estimate of a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime" [26]. To derive the RfD, the US EPA applied benchmark dose (BMD) modeling. In this approach, the dose, termed the *benchmark dose*, is identified at which the prevalence of a defined health abnormality exceeds the background prevalence by a specified amount (i.e., an excess risk). The lower bound of the 95% confidence interval for the BMD, referred to as the BMDL (*benchmark dose lower limit*), is identified. The BMDL is therefore the lowest Hg dose that is statistically consistent with the observed

excess risk. The US EPA considered a neuropsychological test score at the fifth percentile or below to be the critical adverse effect, and a doubling of such scores as the critical excess risk [27]. Based on models of the dose–effect associations relating prenatal MeHg exposure to the target excess risk, the US EPA identified a BMDL of $58 \mu\text{g l}^{-1}$ in cord blood (or 12 ppm of Hg in maternal hair). A total uncertainty factor of 10 was applied to the BMDL to take account of inter-individual toxicokinetic and toxicodynamic variability, resulting in a target cord blood Hg level of $5.8 \mu\text{l}^{-1}$. The next task was to calculate the MeHg intake (i.e., the RfD) that, over a lifetime, would not produce a cord blood Hg level greater than $5.8 \mu\text{l}^{-1}$. To do so, a one-compartment pharmacokinetic model was used, involving the following assumptions: elimination constant, 0.014 days^{-1} ; blood volume, 5 l; MeHg absorption, 0.95; the fraction of absorbed dose in the blood, 0.059; body weight, 67 kg; the ratio of cord blood Hg to maternal blood Hg, 1:1.

The US EPA recognized that the RfD is sensitive to the values assumed for these factors. In the absence of definitive evidence regarding the functional form of the association between Hg body burden and children's neurodevelopment, the EPA's calculations were based on a linear model. Additional analyses of the Faroe Islands study, however, suggested that a log linear model, which would result in a lower value for the RfD, provides a somewhat better fit to the data than does a linear model [28]. Recent analyses indicate that the best point estimate for the ratio of cord blood Hg to maternal blood Hg is 1.7, not 1.1, as the US EPA assumed, and that the ratio at the 95th percentile might be as large as 3.4 [29]. Use of this revised estimate of the ratio would produce a 35% reduction in the RfD. The use of point estimates for the factors considered in the derivation of the RfD ignores the fact that the values on such factors are likely to vary among individuals in the population [30]. The incorporation of information about the distributions of such factors would be important in deriving RfDs that are more protective for potentially susceptible subgroups [27]. Taking account of the inevitable error involved in measuring MeHg exposure, which was not done in the EPA analysis, would also result in a lower RfD [31]. In addition, the findings of some recent studies suggest that the BMDL assumed by the US EPA as the point of departure for calculating the RfD is too high. Hair Hg levels as low as 2 ppm

might be cardiotoxic in adults [32], and adverse neurodevelopmental effects have been observed at maternal hair Hg levels well below the BMDL of 12 ppm [33, 34]. Intake limits for MeHg will therefore need to be reconsidered periodically as new data provide more refined estimates for the assumptions that underlie the risk assessments.

A factor complicating MeHg risk assessment is that seafood, the primary route of human exposure to MeHg, also delivers beneficial nutrients such as omega-3 fatty acids, whose effects on the critical endpoints can be antagonistic to those of MeHg. In other words, the estimate of the association between a health endpoint and MeHg exposure incurred as the result of seafood consumption cannot be interpreted as a “pure” estimate of MeHg toxicity insofar as it reflects the balance between the beneficial effects of some fish constituents and the adverse effects of MeHg on the critical endpoint. The trade-off between the risks and benefits associated with seafood consumption has been demonstrated in studies of children’s neurodevelopment [33] and the progression of cardiovascular disease in adult men [35].

Mercury/Methylmercury Risk

DAVID C. BELLINGER

Microarray Analysis

Microarray Analysis and Genomics

The fields of genetics, combinatorial chemistry, and statistics combine to produce a technology, known as *microarray analysis*, that can be used to quantitatively assess the risk of developing a disease for which the genetic expression has been identified. The technology is one of the cornerstones of the science of functional genomics and produces measurements of the expression levels of genes in a particular organism, generally in response to some condition(s) believed to stimulate the organism's genes. By comparing the expression levels of the full complement of genes from the organism with those from a "normal" individual, one can identify genes that are "differentially expressed" (expressed at different levels in the two genomes). To the extent that a gene has been identified as either causative or highly associated with a particular disease (e.g., *BRCA1* gene on chromosome 17 for suppression of early onset breast cancer tumor, or the *Rb* gene on chromosome 13 for suppression for retinoblastoma tumor), risk of disease can be assessed and mechanisms of causation can be elucidated. In some cases, the analysis may permit early intervention to prevent further disease (e.g., the identification of the absence of a gene may permit early diagnosis and treatment).

Microarray analysis can assist in the quantification of risk in developing disease by virtue of technology that permits measurements of gene expression. If increased gene expression can be associated with increased risk of disease, then accurate measurements of gene expression, and quantification of the uncertainty in these measurements, becomes essential. Thus, a complete understanding of the extent to which microarray analyses quantify disease risk requires clarification of the measurement process, which exposes possible sources of uncertainties in gene expression levels. Also, it is important to note that these measurements reflect levels of messenger ribonucleic acid (mRNA), not the levels of proteins, which the organism manufactures in response to measured elevated levels of mRNA.

Presently, two technologies, one using *complementary deoxyribonucleic acid (cDNA) slides* and the other using *oligonucleotide arrays*, are available for measuring gene expression levels. Both are based

on the biological concept of hybridization between matching nucleotides and both technologies contain multiple copies of single-stranded genes or gene fragments, called *probes*, linked to a substrate or surface for binding with expressed transcripts from target tissues.

Biological Basis and Measurements from Microarrays

The genetic code for an organism is contained in organized strings of four nucleotides (A: adenine, C: cytosine, G: guanine, T: thymine), arranged in triplets such that each triplet codes for one of 20 amino acids. (Multiple triplets may code for the same amino acid.) Strings of amino acids are called *peptides*. Peptides can act independently in a cell, or they can combine with other peptides to form complex proteins used by the organism for cell function. Genetic material known as *deoxyribonucleic acid (DNA)* is arranged in a double-stranded helical structure, with complementary base pairs on either side of the helix. In response to a stimulus to produce a protein, the coding genes in the DNA are transcribed into mRNA for translation into peptides. To test for gene expression, cells from tissues are harvested, and the mRNA is reverse transcribed into its more stable form, cDNA, split into smaller strands, and labeled with a chemical that can be detected by an instrument. For quantitative measurement, the mixture of cDNA strands is placed onto the slide or chip containing the gene probes, and the strands of nucleotides in the target sample are allowed to bind (hybridize) to their matching partners. Spots on the slide or chip where hybridization has occurred indicate genes that are present in larger quantities and may have been expressed in response to the stimulus. With either technology, the reported intensity level at a particular location on the slide or chip is a summary of fluorescence measurements detected in a series of pixels that comprise the spot on the slide.

The two technologies for measuring gene expression differ in the process that is used to manufacture the probes on the slide or chip. In cDNA slides, the probes are obtained from actual cellular DNA that has been spliced using restriction enzymes to cleave the DNA at specific locations corresponding to specific genes. Once isolated, the DNA fragments undergo a series of complex processes that amplify and multiply their numbers, resulting in a gene "library" for

a given laboratory, which is then used to bond to the substrate on slides. In oligonucleotide arrays, the gene fragments consist of “known” strings of manufactured nucleotides that are placed on the chip using photolithography. For both the chip and the slide, as many as 50 000 or more mRNA transcript probes are placed in an array of rows and columns, hence the term *microarray*.

The technologies also differ in the experimental protocol that yields the data on gene expression levels. In cDNA experiments, a target sample contains a mixture of two types of cells, control and experimental, whose mRNA is reverse transcribed into the more stable cDNA and then labeled with two different fluorophores: the control cells are often labeled with cyanine 3, or Cy3 (green dye), and the experimental cells (e.g., cells that have been subjected to some sort of treatment, such as stress, heat, radiation, or chemicals), or those known to originate from a disease tissue, are often labeled with cyanine 5, or Cy5 (red dye). When mRNA concentration is high in these cells, their cDNA will bind to their corresponding probes on the spotted cDNA slide; an optical detector in a laser scanner will measure the fluorescence at wavelengths corresponding to the green and red dyes (532 and 635 nm, respectively). Good experimental design will interchange the dyes in a separate experiment to account for imbalances in the signal intensities from the two types of fluorophores and the expected degradation in the cDNA samples between the first scan at 532 nm (green) and second scan at 635 nm (red). The ratio of the relative abundance of red and green dyes at these two wavelengths on a certain spot indicates relative mRNA concentration between the experimental and control genes. Thus, the gene expression levels in the target cells can be directly compared with those from the control cells.

Oligonucleotide arrays circumvent the possible inaccuracies that can arise in the preparation of a gene “library” and the control and experimental samples for spotted array slides, by using 11–20 predefined and prefabricated sequences of 25–60 nucleotides for each gene. Rather than circular-shaped spots, these probes are deposited onto the chip in square-shaped cells. The probe cells measure 24×24 or $50 \times 50 \mu\text{m}^2$ and are divided in 8×8 pixels; cells from the target sample, labeled again with a fluorophore, will hybridize to those squares on the chip that correspond to the complementary strands of the target sample’s single-stranded cDNA. For these experiments, the

target sample contains only one type of cell (e.g., treatment or control); the assessment of expression is in comparison to the expression level on an adjacent probe, which is exactly the same as the gene probe except for the middle nucleotide (e.g., 13th out of 25 nucleotides). This “mismatch” (MM) for the “perfect match” (PM) sequence is only rough, since a target sample with elevated mRNA concentration for a certain gene may sufficiently hybridize to both the PM and MM probes. However, the results are believed to be less variable, since the probes on the chips are manufactured in more carefully controlled concentrations. Gene expression levels are measured again by a laser scanner that detects the optical energy in the pixels at the various probes (PM and MM) on the chip.

Statistical Analysis of Microarray Measurements

The analysis of the data (fluorescence levels at the various locations on the slide or chip) depends upon the technology. For cDNA experiments, the analysis usually involves the logarithm of the ratio of the expression levels between the target and control samples. For oligonucleotide experiments, the analysis involves a weighted linear combination of the logarithm of the PM expression level and the logarithm of the MM expression level (with some authors choosing zero for the weights of the MM values). Microarray analysis involves several considerations, including the separation of “spot” pixels from “background” pixels and the determination of the expression level from the intensities recorded from the data “spot” pixels; the adjustment of the calculated spot intensity for background (“background correction”); the normalization of the range of fluorescence values from one experiment to another, particularly with oligonucleotide chips; experimental design of multiple slides or chips [1, 2]; data transformations [3, 4], statistical methods of inference and combining information from multiple cDNA experiments [5, 6] and from multiple oligonucleotide arrays [7, 8]; and adjustments for multiple comparisons [9, 10]. The “low-level” analysis consists of the necessary “preprocessing” steps, including data transformation (usually the logarithm) to partially address the non-normality of the expression levels, and normalization and background correction methods to adjust for different signal intensities across different microarray

experiments and sources of variation arising from the chip manufacturing process and background intensity levels. The “high-level” analysis usually involves clustering the gene expression levels into groups of genes that are believed to respond similarly, but no consensus has been achieved on the best methods for normalizing, clustering, and reducing the number of genes to consider as “significantly differentially expressed” when searching for associations between disease and gene locations on chromosomes.

Microarray Analysis in Risk Identification

Microarray analyses have become a standard screening tool in the exploration and elucidation of mechanisms of disease and for studying the interface between the environment and the genome. They also have been used to better understand the effect of certain exposures, such as anthrax, on the cells from human and animal populations, and hence to better characterize the risk of such agents to these populations [11]. As the technology matures and becomes more widely accessible, genome- and proteome-scale microarrays will gain greater acceptance in quantitative risk assessment for many more diseases, vaccines, and other public health initiatives. Examples of useful gene microarray-based investigations that can potentially improve public health practice include discoveries of candidates for biomarkers of disease; measurements of perturbations in the cell cycle under differing conditions; uncovering genetic underpinnings of numerous human, animal, and plant diseases; and explorations of the impacts of environmental change on ecosystems and populations of humans, animals, plants, and disease-causing organisms. An example of the potential utility of microarrays is in the tracking of antigenic drifts and shifts of influenza viruses and the changes in the virus – host relationship. As scientists increase their expertise and knowledge with these types of analyses, and as more results from laboratories are validated in nature, the fields of genomics, proteomics, and further studies of the full complement of cellular components will contribute substantially to how we perceive, measure, and address disease and environmental change.

Mobile Phones and Health Risks

Possible health risks of nonionizing electromagnetic fields (EMF) have been controversially discussed amongst researchers, in politics, and in the public for some time (*see* **Extremely Low Frequency Electric and Magnetic Fields**). The main issue is whether EMF levels below permitted levels, directly or indirectly, yield adverse health effects.

This paper summarizes current epidemiological data on health effects associated with EMF emitted by mobile phones. Up to now little evidence linking short-term mobile phone use to health risks has been found. The health effects of long-term (>10 years) mobile phone use, however, need to be clarified. This is important, as the use of mobile phones is increasing worldwide. Hence, eventual minimum effects regarding health risks could be of public health importance [1, 2].

Current Information on Health Risks of Mobile Phone Use

The majority of epidemiological studies carried out in this area to date have focused on mobile phone use and the possible increased risk of brain tumors. Several case-control (*see* **Case-Control Studies**) and cohort studies (*see* **Cohort Studies**) investigating this association have been published. Initially, these were mainly conducted in the United States, Finland, and Sweden. The studies were difficult to compare, as they investigated different brain tumor types and used different exposure assessment methods. Their results were also not always uniform. These first studies were basically all disadvantaged by the relatively short mobile phone use periods of their participants which did not allow the investigation of long-term mobile phone use.

The World Health Organisation (WHO) is coordinating an international case-control study called *INTERPHONE*, being carried out in 13 countries and incorporating more than 6000 brain tumor cases. Currently, eleven reports of this study have been published, three of which report results for acoustic neuroma, two for glioma only, three for glioma and meningioma, two for glioma, meningioma and

acoustic neuroma and one for parotid gland tumor. None of these studies showed an association between brain tumor risk and mobile phone usage of a duration less than 10 years. A combined study of five “INTERPHONE” countries based on 678 patients with acoustic neuroma and 3533 control persons, however, did show a slight increased risk for long-term mobile phone users (10 years or more) [3]. One of the most recent studies also reported an increased risk for glioma amongst long-term mobile phone users [4]. It should, however, be noted that these preliminary results are not confirmed in the other publications and are based on small numbers. Their results thus need to be affirmed. They will have to be verified when a pooled analysis of all the data from the 13 “INTERPHONE” countries is completed. Combined results from the international study are expected in the near future.

Conclusion

Results of studies that have been published up to date do not show any irrefutable association between mobile phone use and an increased risk of glioma or meningioma. Many of the first studies conducted in this area did not have long-term mobile phone users amongst their participants. The study populations were also small, thus limiting their results. More recent studies have been able to incorporate long-term mobile phone users in their analyses. Although final results of the “INTERPHONE” study, especially regarding long-term mobile phone use are still outstanding, preliminary results lead to the assumption that no definite association will be found in this group either.

Model Risk

Overview

Reliance on models to price, trade, and manage risks carries its own risks. Models are susceptible to errors: from incorrect assumptions about price dynamics and market interactions, from inaccurate estimation of volatilities and correlations and other inputs that are not directly observable and must be forecasted.

Model risk relates to the risks involved in using models to value and hedge securities. Model risk becomes a compelling issue for institutions that trade over-the-counter (OTC) derivative products and execute arbitrage strategies.

In liquid and more or less efficient securities markets, the market price is, on average, the best indicator of the asset's value. In the absence of liquid markets and price discovery mechanisms, there is no other alternative than theoretical valuation models to mark-to-model the position, to assess the risk exposure along the various risk factors, and to derive the appropriate hedging strategy.

Since 1973, with the publication of the Black and Scholes [1] and Merton [2] option-pricing model (*see Risk-Neutral Pricing; Importance and Relevance; Statistical Arbitrage*), we have witnessed relentless increased complexity in the theoretical approach to valuation. The area of fixed income instruments and derivatives is striking. With increased sophistication in the design of securities, like the addition of imbedded options, valuation is now often based on complex multifactor stochastic interest rate models, which are only understood by "rocket scientists".

The pace of model development has accelerated to support the rapid growth of financial innovations such as caps, floors, swaptions (*see Nonparametric Calibration of Derivatives Models*), spread options (*see Credit Migration Matrices*), and other exotic derivatives (*see Equity-Linked Life Insurance; Insurance Pricing/Nonlife*). These innovations have also been made possible because of new developments in financial theory, which allow a better capture of the many facets of financial risks. At the same time, these models would have never been implemented in practice, and not so well accepted on the trading floor, had the growth in computing power not accelerated so dramatically. It seems that financial innovations, model development, and computing

power are engaged in a sort of leapfrog game; financial innovations call for more model complexity, which in turn requires more computing power. Using complex models and huge computing power increases the traders' level of comfort and gives them the incentive to innovate more.

The main causes of model risk are as follows:

- *Model error*

The model might contain mathematical errors or, more likely, be based on simplifying assumptions that are misleading or inappropriate.

- *Implementing a model wrongly*

The model might be implemented wrongly, either by accident or as part of a deliberate fraud.

Model Error

Derivatives trading depends heavily on mathematical models that make use of complex equations and advanced mathematics. In the simplest sense, a model is incorrect if there are mistakes in the analytical solution (in the set of equations, or in the solution of a system of equations).

A model is also said to be incorrect if it is based on wrong assumptions about the underlying asset price process – and this is perhaps both a more common and a more dangerous risk. The history of the financial industry is littered with examples of trading strategies based on shaky assumptions and some model risks are really just a formalization of this kind of mistake. For example, a model of bond pricing might be based on a flat and fixed term structure, at a time when the actual term structure of interest rates is steep and unstable.

The most frequent error in model building is to assume that the distribution of the underlying asset is stationary (i.e., unchanging), when, in fact, it changes over time. The case of volatility is particularly striking. Derivatives practitioners know very well that volatility is not constant. The ideal solution would be to acknowledge that volatility is stochastic and to develop an option-pricing model that is consistent with this, but option-valuation models become computationally difficult when any sort of stochastic volatility is included. (Moreover, introducing new unobservable parameters associated with the volatility process into the valuation model makes the estimation problem even more severe.)

Instead, derivative practitioners find themselves engaged in a continual struggle to find the best compromise between complexity (to better represent reality) and simplicity (to improve the tractability of their modeling).

While traders know that they are making simplifying assumptions about price behavior, it is not easy for them (or for risk managers) to assess the impact of this kind of simplifying assumption on any given position or trading strategy. For example, practitioners often assume that rates of return are normally distributed, i.e., that they have a classic “bell-shaped” distribution. However, empirical evidence points to the existence of “fat tails” in distributions; in these distributions, unlikely events are, in fact, much more common than would be the case if the distributions were normally distributed. Therefore, empirical distributions rather than theoretical distributions should be used to help alleviate the danger of an unrecognized fat tail, where possible. However, such fat tails are not accounted for in the theoretical distributions that lie behind many classic models, such as the Black–Scholes option-pricing model.

Another way to oversimplify a model is to underestimate the number of risk factors that it must take into account. For simple “vanilla” investment products, such as a callable bond, a one-factor term structure model (*see* **Dynamic Financial Analysis; Insurance Applications of Life Tables**), where the factor represents the spot short-term rate, may be enough to produce accurate prices and hedge ratios. For more complex products, such as spread options or exotic structures, a two- or three-factor model may be required, where the factors are, for example, the spot short-term and long-term rates for a two-factor model.

Another problem is that models are almost always derived under the assumption that perfect capital markets exist. In reality, many markets, especially those in less-developed countries, are far from perfect. Meanwhile, even in developed markets, OTC derivative products (*see* **Alternative Risk Transfer; Weather Derivatives**) are not traded publicly and usually cannot be perfectly hedged.

Liquidity, or rather the absence of liquidity, may also be a major source of model risk. Models assume that the underlying asset can be traded long or short at current market prices, and that prices will not change dramatically when the trade is executed.

In the same way, models that are safe to use for certain kinds of product might not perform well

at all on subtly different instruments. Many OTC products have options embedded within them that are ignored in the standard option-pricing model. For example, using a model to value warrants may yield biased results if the warrant is also extendable. Other common errors include using the Black–Scholes option-valuation model to price equity options, while adjusting for dividends by subtracting their present value from the stock price. This ignores the fact that the options can be exercised early. Applying the wrong model is also easy, if the researcher is not clear about whether the underlying instrument is a primary asset or is itself a contingent claim on another asset (or basket of assets).

Implementing a Model Wrongly

Even if a model is correct and is being used to tackle an appropriate problem, there remains the danger that it will be wrongly implemented. With complicated models that require extensive programming, there is always a chance that a programming “bug” may affect the output of the model. Some implementations rely on numerical techniques that exhibit inherent approximation errors and limited ranges of validity. Many programs that seem error-free have been tested only under normal conditions, and so may be error-prone in extreme cases and conditions.

In models that require a Monte Carlo simulation (*see* **Risk Measures and Economic Capital for (Re)insurers; Structured Products and Hybrid Securities; Reliability Optimization**), large inaccuracies in prices and hedge ratios can creep in if insufficient simulation runs or time steps are implemented. In this case, the model might be right, and the data might be accurate, but the results might still be wrong if the computation process is not given the time it needs.

For models evaluating complex derivatives, data are collected from many different sources. The implicit assumption is that for each time period, the data for all relevant assets and rates pertain to exactly the same time instant, and thus reflect simultaneous prices. Using nonsimultaneous price inputs may be necessary for practical reasons, but again, it can lead to wrong pricing.

When implementing a pricing model, statistical tools are used to estimate model parameters such as volatilities and correlations. An important question, then, is how frequently should input parameters be

refreshed? Should the adjustment be made on a periodic basis, or should it be triggered by an important economic event? Similarly, should parameters be adjusted according to qualitative judgments, or should these adjustments be purely based on statistics? The statistical approach is bound to be in some sense “backward looking”, while a human adjustment can be forward looking, i.e., it can take into account a personal assessment of likely future developments in the relevant markets.

All statistical estimators are subject to estimation errors involving the inputs to the pricing model. A major problem in the estimation procedure is the treatment of “outliers”, or extreme observations. Are the outliers really outliers, in the sense that they do not reflect the true distribution? Or are they important observations that should not be dismissed? The results of the estimation procedure will be vastly different depending on how such observations are treated. Each bank, or even each trading desk within a bank, may use a different estimation procedure to estimate the model parameters. Some may use daily closing prices, while others may use transaction data. Whether the researcher uses calendar time (i.e., the actual number of days elapsed), trading time (i.e., the number of days on which the underlying instrument is traded), or economic time (i.e., the number of days during which significant economic events take place) affects the calculation.

Finally, the quality of a model depends heavily on the accuracy of the inputs and parameter values that feed the model. This is particularly true in the case of relatively new markets, where best-practice procedures and controls are still evolving. The old adage “garbage in, garbage out” should never be forgotten when implementing models that require the estimation of several parameters. Volatilities and correlations are the hardest input parameters to judge accurately. For example, an option’s strike price and maturity are fixed, and asset prices and interest rates can be easily observed directly in the market – but volatilities and correlations must be forecast. This gives rise to many opportunities for both genuine mistakes and deliberate tampering that can be countered only through robust control procedures and independent vetting.

The most frequent problems in estimating values, on the one hand, and assessing the potential errors in valuation, on the other hand, are as follows:

- *Inaccurate data*

Most financial institutions use internal data sources as well as external databases. The responsibility for data accuracy is often not clearly assigned. It is therefore very common to find data errors that can significantly affect the estimated parameters.

- *Inappropriate length of sampling period*

Adding more observations improves the power of statistical tests and tends to reduce the estimation errors; but, the longer the sampling period, the more weight is given to potentially stale and obsolete information. Especially in dynamically changing financial markets, “old” data can become irrelevant and may introduce noise into the estimation process.

- *Problems with liquidity and the bid/ask spread*

In some markets, a robust market price does not exist. The gap between the bid and ask prices may be large enough to complicate the process of finding a single value. Choices made about the price data at the time of data selection can have a major impact on the output of the model.

How Can We Mitigate Model Risk?

One important way to mitigate model risk is to invest in research to improve models and to develop better statistical tools. It is critical for a financial institution to keep up with the latest developments and to spread new knowledge quickly throughout the business.

An even more vital way of reducing model risk is to establish a process for independent vetting of how models are both selected and constructed. This should be complemented by independent oversight of the profit and loss (P&L) calculation.

The role of vetting is to offer assurance to the firm’s management that any model for the valuation of a given security proposed by, say, a trading desk is reasonable. In other words, it provides assurance that the model offers a reasonable representation of how the market itself values the instrument, and that the model has been correctly implemented. Vetting should consist of the following phases:

1. Documentation

The vetting team should ask for full documentation of the model, including both the assumptions underlying the model and its mathematical expression. This should be independent of any particular implementation, such as a spreadsheet or a C++ computer code, and should include

(a) the term sheet or, equivalently, a complete description of the transaction;

(b) a mathematical statement of the model, which should include

(i) an explicit statement of all the components of the model: stochastic variables and their processes, parameters, equations, and so on;

(ii) the payoff function and/or any pricing algorithm for complex structured deals;

(iii) the calibration procedure for the model parameters;

(iv) the hedge ratios/sensitivities;

(v) implementation features, i.e., inputs, outputs, and numerical methods employed;

(vi) a working version of the implementation.

2. Soundness of model

The model vetter needs to verify that the mathematical model is a reasonable representation of the instrument that is being valued. For example, the manager might reasonably accept the use of a particular model (e.g., the Black model) for valuing a short-term option on a long-maturity bond, but reject (without even looking at the computer code) the use of the same model to value a 2-year option on a 3-year bond. At this stage, the risk manager should concentrate on the finance aspects and not become overly focused on the mathematics.

3. Independent access to financial rates

The model vetter should check that the bank's middle office has independent access to an independent market-risk-management financial rates database (to facilitate independent parameter estimation).

4. Benchmark modeling

The model vetter should develop a benchmark model based on the assumptions that are being made and on the specifications of the deal. Here, the model vetter may use an implementation that is different from the implementation that is being proposed. A proposed analytical model can be tested against a numerical approximation technique or against a simulation approach. (For example, if the model to be vetted is based on a "tree" implementation, one may rely on the partial differential equation approach instead and use the finite-element technique to derive the numerical results.) Compare the results of the benchmark test with those of the proposed model.

5. Health check and stress test the model

Also, make sure that the model possesses the basic properties that all derivatives models should possess, such as put-call parity and other nonarbitrage conditions. Finally, the vetter should stress test the model. The model can be stress tested by looking at some limit scenario in order to identify the range of parameter values for which the model provides accurate pricing. This is especially important for implementations that rely on numerical techniques.

6. Build a formal treatment of model risk into the overall risk-management procedures, and periodically reevaluate models

Also, reestimate parameters using best-practice statistical procedures. Experience shows that simple, but robust, models tend to work better than more ambitious, but fragile, models. It is essential to monitor and control model performance over time.

Conclusion

Models are an inevitable feature of modern finance, and model risk is inherent in the use of models. The most important aspect is to be aware of the dangers. Firms must avoid placing undue faith in model values, and must hunt down all the possible sources of inaccuracy in a model. In particular, they must learn to think through situations in which the failure of a model might have a significant impact.

We have stressed the technical elements of model risk, but we should also be wary of the human factor in model risk losses. Large trading profits tend to lead to large bonuses for senior managers, and this creates an incentive for these managers to believe the traders who are reporting the profits (rather than the risk managers or other critics who might be questioning the reported profits). Often, traders use their expertise in formal pricing models to confound any internal critics, or they may claim to have some sort of informal but profound insight into how markets behave. The psychology of this behavior is such that we are tempted to call it the "Tinkerbell" phenomenon, after the scene in *Peter Pan* in which the children in the audience shout, "I believe, I believe" in order to revive the poisoned fairy Tinkerbell. The antidote is for senior managers to approach any model that seems to record or deliver above-market returns with a healthy skepticism, to insist that models are made

transparent, and to make sure that all models are independently vetted. The topic of model risk is discussed in detail in [3]. Also, many articles on this subject appear in [4].

The comments on model risk in this chapter are made in the context of a trading environment. But, they can be easily transposed in other contexts such as risk management.

AND ROBERT MARK

Modifiable Areal Unit Problem (MAUP)

Geographical scale and spatial resolution are important considerations in the design, implementation, and interpretation of research studies aimed at understanding the link between environmental hazards and related adverse effects on people and ecosystems [1] (see **Geographic Disease Risk; Spatiotemporal Risk Analysis**). Sources of pollution, ambient pollutant concentrations, population exposure levels, and occurrence of environmentally related adverse effects all vary according to spatial scale and resolution – where “scale” refers to the spatial (or areal) extent of the analysis and “resolution” identifies the level of aggregation for statistical data gathering. The range of geographical scales typically applied to environmental exposure studies ranges from personal exposure investigations where emphasis is on pollutant concentrations within a few centimeters of a person’s body (10^{-1} km) to studies of global exposure to UV radiation that encompass continents, if not the entire world (10^4 km). The scope of statistical aggregation for health outcome data is illustrated by information collected by the US census, which reports data at the block, block group, tract, minor civil division or MCD, county, state, and regional levels.

Spatial (geographical) data on environmental health are often aggregated to make communication of research results convenient and informative. The modifiable areal unit problem or *MAUP* is a term coined by geographers to describe a potential source of error that can affect spatial studies using aggregate sources of data [2, 3]. The MAUP is a formal statement of the fact that statistical results can and do vary by (a) scale – the number of spatial units (or zones) used in the analysis and (b) aggregation – the grouping of smaller geographical areas into larger spatial units. Thus a variable that is significant in a regression analysis at one geographic scale may be insignificant at another, or a spatial pattern of data points that appears random at one level of aggregation may seem clustered at another.

Among other problems, the MAUP can contribute to a misinterpretation of aggregate data by which incorrect inferences about the nature of individuals

are based exclusively on combined statistics from the group to which those individuals belong. This mistake is called the *ecological fallacy*, where the fallacy lies in assuming that all group members have specific characteristics of the larger group (e.g., assuming that all basketball players are tall or that everyone from Ireland has red hair). The fact that statistical findings from analysis of aggregate spatial data depend on subjective and often arbitrary decisions about geographic scale and resolution is a sobering reality, especially given that results often serve as the basis for risk management decisions, public policy choices, and communication strategies.

Public health professionals have known about the MAUP for years and routinely recognize the importance of addressing spatial issues [1]. Exposure analysts, for example, must deal with the uneven geographical distribution of people and pollution and they direct significant resources toward estimating exposures in ways that will minimize misclassification errors. Biostatisticians know that the MAUP can affect statistical analysis of exposure–response relationships and they therefore take steps to deal with issues of misaligned data, data incompatibility, and validity of inferences. Epidemiologists are trained to take account of spatial scale and resolution in designing studies, and they are cognizant of the need to avoid the ecological fallacy when interpreting findings. Ultimately, the development of suitable statistical frameworks and models along with practical guidance on choosing appropriate spatial units and aggregation levels will be necessary to solve MAUP-related quandaries.

Scientists today continue to examine the MAUP and its impact on research design and interpretation of scientific findings. For example, although the study of geographical patterns in cancer prevalence and/or incidence has shed much light on disease control and prevention, there is still no scientific consensus on how best to designate geospatial locations of health events (i.e., geocoding) so that results are accurate (within acceptable error), precise (to a desired areal unit of analysis), and “fit for use” (applicable to other available data) [4]. Thus researchers must choose, based on pragmatic rather than scientific considerations, between using smaller areal units that contain few at-risk subjects and yield less reliable rates or larger areal units that may blur meaningful variation occurring within locales. A recent study by Gregorio and his colleagues [4] suggests that if

surveillance of small area cancer clusters is not the goal, then the costs of obtaining and preparing data at spatial units smaller than the census tract may not be justified.

As Sheppard *et al.* [5] point out, results of spatial analysis of *environmental justice* (see **Statistics for Environmental Justice**) issues (i.e., questions of whether poor minority populations bear a disproportionate burden of pollution) are dependent on choices of geographic scale of the unit of analysis (e.g., municipalities, counties, metropolitan areas, and states) and spatial resolution of data within each unit (e.g., zip codes, census tracts, and block groups). Thus individual environmental justice studies may be independently accurate, but give apparently contradictory results, (which are in fact not conflicting), if proper account is not taken of the effect of diverse spatial scales and levels of resolution on analytical outcomes.

To illustrate the types of difficulties created by the MAUP, consider two examples. First, imagine a hypothetical town of four people, all of whom are exposed to a particular environmental pollutant. As shown in Figure 1, two residents live north of a river dividing the town and two live south. Both (a) the disease outcomes actually experienced by the people in the town during the study period and (b) the potential disease outcomes that would have occurred if no one was exposed to the environmental pollutant are

Figure 1 The implications of spatial scale for causal inference – comparison of observed and potential disease outcomes for a hypothetical town during a specified period of observation under two different exposure scenarios [Reproduced from [1]. © Taylor & Francis Group, 2002.]

depicted. The causal incidence proportion ratio (IPR) is a parameter used by epidemiologists to compare the incidence proportion (risk) of disease that a target population would experience during a specified period under two different exposure conditions. It is interpreted as the proportionate increase in risk for the target population over the study period that is caused by the differences in the two exposure conditions. The important point is that the IPR changes depending on the spatial scale. For people north of

Figure 2 The implications of spatial scale for disease clustering – the same number and relative positioning of disease cases can appear random at one scale and clustered at another [Reproduced from [1]. © Taylor & Francis Group, 2002.]

the river, the risk of disease is 1 (two people/two people with the disease) if they are exposed and 0.5 (1/2) if they are not, which means the IPR is equal to 2 (1/0.5). On the other hand, the risk for the two people south of the river is 0.5 (1/2) if exposed and also 0.5 (1/2) if not exposed, which makes the IPR equal to 1. When the entire town is considered, the IPR becomes 1.5 (0.75/0.5) based on a 0.75 (3/4) risk of disease if exposed, and a 0.5 (2/4) risk if not exposed [1].

Second, consider an investigation of the pattern of disease incidence in an area where the population is suspected of being exposed to a toxic environmental agent, while others in outlying areas are thought not to be exposed. An analyst typically will assign a location (e.g., residential address) to each person who has the disease thought to be caused by the environmental agent. Statistical techniques are then used to look for a spatial pattern of disease cases that might suggest a higher incidence in the area of putative exposure. Detecting a “disease cluster” in the area where people are likely to be exposed provides suggestive evidence that the “cluster” is an environmentally induced effect. However, as shown in Figure 2, even though the number and pattern of disease cases remains the same, they can appear random at one scale and clustered at another [1].

In summary, issues of spatial scale and resolution are an intrinsic part of protecting and enhancing environmental health. The MAUP has important ramifications for the design and interpretation of studies

aimed at increasing our knowledge and furthering our understanding of environmental exposures and environmentally induced effects. Ultimately, sound policies to safeguard public health and protect environmental quality depend on our ability to make the right choices about spatial units of analysis and levels of data aggregation within those units.

Molecular Markers and Models

Our understanding of the mechanisms underlying cellular processes, the interactions of these various processes, and the ways in which abrogation of one or more of these processes can lead to adverse health outcomes has increased enormously over the past decade. In addition, a considerable effort is being expended in trying to determine how environmental agents (particularly chemicals, nanomaterials, radiation, and microbes) can play a role in this abrogation of cellular processes, and in turn enhance the disease process (*see Environmental Health Risk; Environmental Hazard; Gene–Environment Interaction*). The challenge is how to bring together these two components – mechanistic understanding of disease outcomes and the impact of environmental agents – in the science of risk assessment. This linkage has been addressed in a formal manner through the US Environmental Protection Agency’s *Guidelines for Carcinogen Risk Assessment* [1] as well as in a preliminary manner by the European Commission in its *First Report on the Harmonization of Risk Assessment Procedures* (ec.europa.eu/food/fs/sc/ssc/out83_en.pdf). A concise review of the history and practices of quantitative-risk assessment has been presented by Hrudey [2]. The main component of this linkage is that the use of mechanistic data in cancer-risk assessment is encouraged to reduce uncertainty, in particular the uncertainty that is associated with any default approach. A similar approach can be applied to risk assessments for other adverse outcomes, including reproductive, neurological, and developmental disorders. This chapter addresses the general types of approaches that can be used for incorporating mechanistic data into quantitative-risk assessments, and the types of data that would help enhance these approaches. There will be an emphasis on cancer risk in order to focus the discussion.

Definition of Terms

A number of terms are used in the context of risk assessment that need to be defined for the purposes of comprehension of their subsequent use.

Mode of action (MOA): is described by a sequence of key events and processes, starting with interaction of an agent with a cell, proceeding through functional and anatomical changes, and resulting in cancer formation [1] (e.g., DNA reactivity, mitogenesis, cytotoxicity with regenerative cell proliferation, immune suppression, and receptor-mediated events).

Mechanism of action: implies a more detailed understating and description of events, often at the molecular level, than is meant by MOA.

Key event: an empirically observable precursor step that is itself a necessary element of the MOA or is a biologically based marker for such an element [1]. For cancer formation, a scheme for the key events whereby a DNA-reactive carcinogen induces tumors has been presented recently by Preston and Williams [3]. It is presented here as an example of the types of key events that could prove to be necessary for molecular-modeling approaches (Table 1). Key events along the pathway to tumor development for DNA-reactive carcinogens, for example, can be assessed both qualitatively and quantitatively by experimental studies and, where possible, by human studies (*see Environmental Carcinogenesis Risk*). The general approach is to establish the relevance to humans of an MoA developed for an animal model, for which data are likely to be more readily available, using the human relevance framework [4].

Key Events and Molecular Markers

In the previous section, a set of key events is presented for tumor production, in general, for exposures to DNA-reactive carcinogens. This same approach can be used for developing a set of key events for non-DNA-reactive (but mutagenic) chemicals. In this case, DNA damage is produced in the absence of covalent binding or other direct DNA–chemical interaction. Once DNA damage is produced, the remaining key events (3–10) are the same as for DNA-reactive carcinogens. The same general principles can be applied for defining MOA in terms of key events for noncancer endpoints. In this situation, however, the key events tend to be chemical specific rather than adverse-outcome specific because of the difficulty of identifying a set of key events for noncancer outcomes. The approach is described in a set of articles in a recent volume of *Critical Review in Toxicology* [5]. As more is learned about

Table 1 Key events for tumor development: DNA-reactive MOAs^(a)

1	Exposure of target cells (e.g., stem cells) to ultimate DNA-reactive and mutagenic species – in some cases this requires metabolism
2	Reaction with DNA in target cells to produce DNA damage
3	Misreplication on damaged DNA template or misrepair of DNA damage
4	Mutations in critical genes in replicating target cell
5	These mutations result in initiation of new DNA/cell replication
6	New cell replication leads to clonal expansion of mutant cells
7	DNA replication can lead to further mutations in critical genes
8	Imbalanced and uncontrolled clonal growth of mutant cells may lead to preneoplastic lesions
9	Progression of preneoplastic cells results in emergence of overt neoplasms, solid tumors (which require neoangiogenesis), or leukemia
10	Additional mutations in critical genes as a result of uncontrolled cell division results in malignant behavior

^(a) Reproduced from [3]. © John Wiley & Sons, Inc., 2005

the specific mechanisms underlying reproductive, developmental, and neurological disorders and the potential role of exposure to environmental agents, it is likely that a set of key events can be developed for any particular outcome. This will certainly enhance the risk-assessment process for these non-cancer diseases.

The great value of using key events in a risk-assessment process is that information gathered on the response of a key event to an environmental stressor is, by definition, informative of the impact of that same stressor on disease induction. Thus, key events, or more likely, a combination of several key events, can be used for the various extrapolations that are a requirement for risk assessment. Such extrapolations include high to low dose, species to species, and acute to chronic exposures, and are frequently the “Achilles heel” of the risk-assessment process [6]. In this regard, it is important to note that considerable caution has to be taken when extrapolating from data obtained with animal models of human diseases to predict disease outcomes in humans. There are frequently significant differences in the specifics of disease formation between humans and animals, even for the same apparent disease.

The recent, very significant enhancement of the ability to unravel the processes underlying a range of diseases at the molecular level has been a consequence of the advances in molecular biology techniques, computational approaches to data analysis, and the development of systems-based models. These together have allowed for a definition of adverse health outcomes, particularly cancer, in terms of key molecular markers.

A very clear example of the application of such approaches is the development of a “universal” tumor model described by Hanahan and Weinberg [7] in their *Hallmarks of Cancer*. This model consists of a set of six acquired characteristics that are essential for the formation of all tumors, irrespective of tumor type and species. These characteristics are broadly described as follows: self-sufficiency in growth signals, insensitivity to antigrowth signals, evasion of apoptosis, limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis. It seems probable that there is no specific order for obtaining these characteristics, although it might be predicted that changes in growth signaling will occur early on in the process. This model has been elegantly extended by Hahn and Weinberg [8]. They described an approach for modeling the molecular circuitry of cancer, whereby a comparison is made of the shared and unique elements (based on the acquired characteristics) of human and mouse models of cancer to aid in the identification of the molecular circuits that function differently in humans and mice. This knowledge can then be used to improve existing models of cancer. An interactive website (<http://www.nature.com/nrc/poster/subpathways/index.html>) utilized a so-called subway map of cancer pathways, and allows the user to investigate specific pathways along the route to cancer. These various models for describing pathways to tumorigenesis based on the identification of key events is synthesized in a comprehensive review by Hahn and Weinberg, *Rules for Making Human Tumor Cells* [9].

It is likely that the most informative key events for tumor development following exposures to environmental chemicals are to be found within the set of

rules for making human (or rodent) tumor cells. The more proximate a key event is to the development of a tumor itself (i.e., it is itself on the pathway to tumorigenesis), the more likely it is that it can be used to predict tumor outcomes both qualitatively and quantitatively. This application is critical for predicting tumor responses at doses below those at which tumors themselves are observed, and for predicting human tumor frequencies from rodent tumor responses. These are essential steps in cancer-risk assessment because the essential epidemiological data are almost always lacking for exposures to environmental chemicals (*see Environmental Risks*).

Molecular Models and Systems Approaches

The development of diseases is a complex process that involves whole organ or tissue responses, even if much of the pertinent data might be collected at the single cell/single pathway level or from averaged responses at the cell population level. What is really needed for risk assessment is a systems approach, where a disease outcome is described by modifications to and abrogations of a system (cellular, tissue, or even whole organism) in response to environmental chemicals. At this juncture, we are some distance away from meeting this need, but there are certainly encouraging steps along this path. A very informative review on the approaches for incorporating quantitative modeling into cell biology is provided by Mogilner *et al.* [10]. They discuss the utility of models of cell signaling, cytoskeletal self-organization, nuclear transport, and the cell cycle. These are all basic cell functions whose abrogation is involved in disease pathways. Thus, a model of normal biology is essential before embarking on the assessment of effects of dysfunction in any of these fundamental processes.

In a similar vein, Mogilner *et al.* [11] have developed a molecular model of mitosis and the mechanisms by which sister chromatids are segregated. In particular, they combine mathematical models and computer simulations together with experimental studies to describe the molecular mechanisms by which the spindle machinery performs its critical functions. Chromosome gains and losses are a significant component of the formation of all tumors, and a high proportion of birth defects and reproductive loss, and so knowledge of the normal process of

mitosis and how this might be disrupted can form an informative component of risk assessments.

On an even broader basis, Kleppe *et al.* [12] have addressed the issue of how signal transduction is orchestrated at the molecular level, which is essential to the understanding of most, if not all, cellular functions. The investigators' approach is to take advantage of high-throughput methods in proteomics and genomics that provide quantitative and temporal information. Such data are integrated to generate predictive models of cellular processes. The authors argue (appropriately) that the generation of such models provides powerful tools for understanding how systems operate in healthy and pathologic states.

Finally, sophisticated computational models can be used to identify key events on the basis of whole genome analysis. These types of models can be used to compare essential functions and their controls across species. Lehner *et al.* [13] have developed such an approach for the systematic mapping of genetic interactions in *C. elegans* to identify common modifiers of diverse signaling pathways. They note that most heritable traits, including disease susceptibility, are impacted by interactions between multiple genes. To test such a hypothesis, Lehner *et al.* used RNA interference to systematically test about 65 000 pairs of genes for their interaction potential. This approach has led to the identification of about 350 genetic interactions among genes involved in signaling pathways that are also mutated in human diseases. Of particular note, in the context of potential key events, the authors identified a class of "highly connected 'hub' genes". If one of these "hub" genes is inactivated it can enhance the phenotypic effects of mutations in a range of different genes. These hub genes *all* encode chromatin modulators, and this activity appears to be conserved across animal species. It is possible that these chromatin modulator hub genes could act as modifier genes in multiple, mechanistically unrelated genetic diseases in humans. This view is supported by studies that link chromatin modulation with human diseases (reviewed in [14]). This type of molecular modeling at the systems level is clearly one of the ways forward for better defining the cellular "master genes" and, when their functions are modified, their role in disease etiology. The subsequent application of such systems-based models to a risk-assessment process that incorporates the use of mechanistic data is both clear to see and inevitable.

Acknowledgments

I wish to thank Dr Stephen Edwards and Dr Rory Conolly for their very insightful review of this manuscript. I also thank Carolyn Fowler for her expert assistance in the preparation of the manuscript.

This manuscript has been reviewed in accordance with the U.S. Environmental Protection Agency policy and approved for publication although it does not necessarily reflect Agency policy.

Monte Carlo Methods

Monte Carlo techniques are used in situations in which the analytic solution of the problem is either intractable or time consuming. Instead of calculating exact quantities, simulation is used to produce stochastic approximations to the solution.

In practice, Monte Carlo methods are discussed interchangeably with simulation. Useful discussions can be found in a variety of monographs, such as [1–3], to which the reader is referred for a thorough review.

Monte Carlo techniques are used in a wide range of problems such as the construction of Monte Carlo hypothesis tests, bootstrap distributions, and for numerical integration in Bayesian calculations (*see Bayesian Statistics in Quantitative Risk Assessment*). More specialized uses are the analysis of complex stochastic systems.

Monte Carlo techniques have a long history in mathematics. An early example is Buffon's Needle dating from 1733, described in [1]. Realistically, the widespread application of Monte Carlo techniques has only become feasible with the availability of cheap and efficient computing since the 1970s. In fact, the exponential increase in available computing power has led to Monte Carlo techniques facilitating major statistical advances.

As a trivial example of a Monte Carlo method, we consider the calculation of the mean μ of a density $g(x)$. The analytic solution is

$$\mu = \int x g(x) dx \quad (1)$$

which may be difficult to evaluate. In the Monte Carlo approach, we sample k observations, $X_1, \dots, X_k$, from $g(x)$ and form the Monte Carlo estimate

$$\hat{\mu} = \frac{\sum_{i=1}^k X_i}{k} \quad (2)$$

A law of large numbers can be used to show that this estimate will converge strongly to the true value, provided the integral exists. Thus, we can produce an estimate of a required accuracy by manipulating k .

An important point to note is that the term *Monte Carlo* refers not to a particular stochastic algorithm

but only to the fact that a stochastic algorithm has been used. For instance, in the previous example there are infinite number of different stochastic algorithms that we could use to sample the observations and estimate μ .

The choice of algorithm depends on a variety of factors. In many problems, there is a “natural” formulation. For example, we estimate the mean of a distribution by taking the mean of a sample from the distribution. Another criterion that should be considered when choosing an algorithm is the efficiency of the method. This leads to the contemplation of variance reduction techniques, which are used to produce more accurate estimates for the same computational effort.

In practice, there is a trade-off between the use of an inefficient algorithm that is easy to design and implement and an efficient algorithm that could take detailed analysis to design. Provided that the inefficient algorithm is not pathological, it is sufficient merely to run the algorithm for an appropriately longer period of time to obtain results comparable to those with the efficient algorithm. An important caveat is that great care must be taken to ensure that satisfactory convergence has occurred. In any application, the relevant literature should be consulted.

We now briefly describe several important examples of the use of Monte Carlo techniques.

Monte Carlo Hypothesis Testing

The first technique considered is that of Monte Carlo hypothesis testing. Assume we have a statistic T , and a simple null hypothesis H_0 and composite alternative H_a . Consider constructing a test of size $1 - \alpha$. If the sampling distribution of $T|H_0$ is known and analytically tractable, then we can use standard calculus methods to construct a critical region for rejecting H_0 .

Alternatively, we consider constructing a Monte Carlo test of H_0 . Specification of the rejection region involves the calculation of a quantile of the null distribution of T . In the Monte Carlo approach, we estimate the required quantile stochastically. To do this we sample from the distribution $h(t)$ of $T|H_0$, to produce $T_1, \dots, T_k$. Depending on the alternative, we reject H_0 if the observed t is more “extreme” than $100(1 - \alpha)\%$ of the combined simulated values and the observed t .

As a simple example, we consider the one sample t test that the mean of a normal distribution is μ against the alternative that it is less than μ . If we observe a sample $X_1, \dots, X_n$, then our statistic is

$$T = \frac{\bar{X} - \mu}{\text{se}} \quad (3)$$

with

$$\text{se} = \frac{\sqrt{\sum_{i=1}^n (X_i - \bar{X})^2}}{n(n-1)} \quad (4)$$

the standard error of the mean. Using the classical approach, we calculate that the rejection region under the null distribution is $t < t_{\alpha, n-1}$, where $t_{\alpha, n-1}$ is the α quantile of Student's t distribution, with $n-1$ degrees of freedom.

Under a Monte Carlo approach we could sample $T_1, \dots, T_k$ from a t distribution with $n-1$ degrees of freedom. We would then reject H_0 if T is less than $T_{[\alpha]}$, where $T_{[\alpha]}$ is the α quantile of $(T_1, \dots, T_k, T)$. Thus, we use the sample from the t distribution to estimate the α quantile.

Alternatively, we can consider the problem of estimating the P value of the test. In the example given, this is equivalent to finding the value of the integral

$$\int_{-\infty}^t h(x) dx \quad (5)$$

which is consistently estimated by

$$\hat{P} = \frac{\sum_{i=1}^k I(T_i \leq t)}{k+1} \quad (6)$$

where $I(T_i \leq t)$ is the indicator function for the event $T_i \leq t$ and $\hat{P}$ is the Monte Carlo estimate.

In practice, the Monte Carlo approach to hypothesis testing is advantageous if the distribution of the chosen test statistic is intractable; however, it is convenient to sample from this distribution. Some practical examples can be found in [4].

Jöckel [5] has investigated the properties of Monte Carlo hypothesis tests under quite general conditions and produced the following conclusions. First, if we choose large enough samples (k) to produce our Monte Carlo quantities, then the results will

be equivalent to the analytic results, with high probability. Secondly, the power of the Monte Carlo test is an increasing function of k .

Bootstrap

The second example we consider is the bootstrap [6]. The bootstrap is a simple but powerful idea that is applicable to a wide range of problems. The central idea of the bootstrap is the following [7]. Suppose we wish to estimate some functional θ of a distribution $F(\beta; x)$,

$$\theta = \int g(x) dF(\beta; x) \quad (7)$$

The bootstrap estimate is found by replacing the unknown population distribution in the integral with the sample's empirical distribution, as follows:

$$\hat{\theta} = \int g(x) d\hat{F}(x) \quad (8)$$

where $\hat{F}(x)$ is the empirical distribution of the observed sample.

Now consider estimating the variability of this statistic. To estimate the variance of the sampling distribution of our estimate, we again replace the population distribution with the sample distribution to give

$$\hat{\sigma}^2 = E_{\hat{F}}[\hat{\theta} - E_{\hat{F}}(\hat{\theta})]^2 \quad (9)$$

where $\hat{\sigma}^2$ is called the *bootstrap estimate* of the sampling variation of $\hat{\theta}$ and $E_{\hat{F}}$ denotes expectation over the empirical distribution of the sample. This calculation could be performed analytically, and requires tabulating a complicated set of permutations. Instead, we can form a Monte Carlo estimate by generating draws of the same size as the original sample from the empirical distribution of the sample. For each such draw, we calculate this statistic. We iterate this procedure k times to obtain $\theta_1^*, \dots, \theta_k^*$, and then calculate

$$\hat{\sigma}^2 = \frac{1}{k} \sum_{i=1}^k (\theta_i^* - \bar{\theta}^*)^2 \quad (10)$$

where $\bar{\theta}^*$ is the mean of the bootstrap samples.

This is equivalent to drawing with replacement from the original sample, which is how the bootstrap is sometimes described.

Complex Systems

Another example of the use of Monte Carlo methods is in the analysis of complicated systems. Simulation methods are often used to explore the properties of complex systems, likelihoods, or estimators. Deterministic simulation systems are frequently used in areas such as finance where the impact of varying input parameters is assessed by changing the values in a spreadsheet [8].

Simulations involving stochastic components are often called *Monte Carlo simulations*. In many situations, uncertainty or randomness plays a key role in the dynamics of the system. Examples include queuing for operations and the demand for inventory items. Mathematical models can be proposed and analytical solutions can be sought, but in any realistic formulation the mathematics quickly becomes intractable.

Epidemic theory has been a fertile area for Monte Carlo simulations. A recent epidemic that has received considerable attention is the HIV/AIDS epidemic. Monte Carlo methods have been used to build realistic behavior patterns into a model for this epidemic and to explore its evolution based on these assumptions. Monte Carlo has also been used as an estimation technique. Often, good information exists for some aspects of the model. The other parameters of the model are varied until the results of the simulation agree best with the observed data.

An example of this methodology is given in [9] and [10]. Data from homosexual men in San Francisco provided input parameters for several aspects of the model. The model was a compartmental one with different levels of sexual activity, immigration, emigration, and death. Data on the probability of transmission related to sexual activity collected from several other studies were used to complement the primary data set.

The simulation study generated incidence projections for HIV/AIDS. A sensitivity analysis was conducted to see the range of behavior variables that were consistent with the observed incidence patterns. The conclusion was that there was a range of parameter values that could generate the observed data. The most important outcome of the analysis was the flagging of the most influential parameters for further collection of data.

Markov Chain Monte Carlo

The final example we consider is the use of Markov chain Monte Carlo (MCMC) techniques such as Gibbs sampling. These techniques use stochastic simulation to explore and summarize a multivariate density that may not be analytically tractable. This problem arises often in the area of Bayesian statistics.

With MCMC techniques, standard results [3] are used to construct Markov chains with the required stationary distributions. Popular choices are variants on the Metropolis–Hastings algorithm. From an initial state vector, the chain is simulated until the sequence reaches approximate stationarity. This is the Monte Carlo part of the algorithm. The resulting sequence is used to make stochastic approximations to any required functional of the multivariate distribution.

Moral Hazard

Policyholder Behavior

Providing insurance protection to an individual may lead that person to behave more carelessly than he or she did before having coverage. If the insurer cannot predict this behavior and relies on past loss data from uninsured individuals to estimate rates, the resulting premium is likely to be too low to cover losses.

Moral hazard refers to an increase in the probability of loss caused by the behavior of the policyholder. Obviously, it is extremely difficult to monitor and control behavior once a person is insured. How does one monitor carelessness? Is it possible to determine whether a person might decide to collect more on a policy than he or she deserves by making false claims?

Probability of Loss Increases after a Person Becomes Insured

The numerical example used to illustrate adverse selection can also demonstrate moral hazard. With adverse selection, the insurer cannot distinguish between good and bad risks, but the probability of a loss for each group is assumed not to change after a policy is sold. With moral hazard, the actual probability of a loss becomes higher after a person becomes insured. For example, suppose the probability of a loss increases from $p = 0.1$ before insurance to $p = 0.3$ after coverage has been purchased. If the insurance company does not know that moral hazard exists, it would sell policies at a price of \$10 to reflect the estimated actuarial loss ($0.1 \times \$100$). The actual loss would be \$30 since p has increased to 0.3. Therefore, the firm would lose \$20 ($\$30 - \10) on each policy it sells.

Mechanisms to Avoid Losses from Moral Hazards

One way to avoid the problem of moral hazard is to raise the premium to \$30 to reflect the known increase in the probability p , that occurs once a policy has

been purchased. In this case, there is *no* decrease in coverage as there was in the adverse selection example. Those individuals willing to buy coverage at a price of \$10 would still want to buy a policy at \$30 since they know that their probability of a loss with insurance would be 0.3.

Another way to avoid moral hazard is to introduce *deductibles* and *coinsurance* as part of the insurance contract. A sufficiently large deductible can act as an incentive for the insureds to continue to behave carefully after purchasing coverage because they would be forced to cover a significant portion of their loss themselves. With coinsurance, the insurer and the insured share the loss together. An 80% coinsurance clause in an insurance policy means that the insurer pays 80% of the loss (above a deductible), and the insured pays the other 20%. As with a deductible, this type of risk-sharing arrangement encourages safer behavior because those insured want to avoid having to pay for some of the losses.^a Another way to encourage safer behavior is to place upper limits on the amount of coverage an individual or enterprise can purchase. If the insurer provides only \$500,000 worth of coverage on a structure and contents worth \$1 million, then the insured knows that he or she would have to incur any residual costs of losses above \$500,000. This assumes that the insured is not able to purchase a second insurance policy for \$500,000 to supplement the first one and hence be fully protected against a loss of \$1 million, except for deductibles and insurance clauses.

Even with these clauses in an insurance contract, the insureds may still behave more carelessly with coverage than without it simply because they are protected against a large portion of the loss. For example, they may decide not to take precautionary measures that they would have adopted had they been uninsured. The cost of adopting mitigation may now be viewed as too high relative to the dollar benefits that the insured would receive from this investment. If the insurer knows in advance that an individual would be less interested in loss-reduction activity after purchasing a policy, then it can charge a higher insurance premium to reflect this increased risk or it can require specific mitigation measures as a condition of insurance. In either case, this aspect of the moral hazard problem is overcome.

End Notes

^a. For more details on deductibles and coinsurance in relation to moral hazard, see Pauly [1].

Multiattribute Modeling

Attributes, Criteria, and Objectives

In the context of decision aid or support, Roy [1] defines a *criterion* as “a tool constructed for evaluating and comparing potential actions according to a point of view that must be (as far as it is possible) well defined”. This concept is exploited in the approach to complex decision making and planning problems that has been termed *Multiple Criteria Decision Analysis* or *Aid (MCDA)*, or *Multiple Criteria Decision Making (MCDM)*. See Keeney and Raiffa [2] for early developments in this field, and Belton and Stewart [3] for a more recent and general review.

The fundamental paradigmatic basis underlying MCDA/MCDM is first to identify the appropriate criteria against which alternative courses of action or policies may be evaluated and compared in more-or-less unambiguous terms, before seeking to construct an aggregate measure of preference that integrates performance across all criteria. It is within this process that we introduce the concept of multiple attributes, or *multiattribute modeling*. Although there may not be absolute uniformity concerning terminology in the literature, it is a useful and quite common practice to adopt the following definitions:

- *Criterion*

A perspective according to which, decision alternatives may be evaluated, representing some specific interest, concern or point of view, perhaps associated with a particular stakeholder group.

- *Attribute*

An evaluation or measure of performance of a decision alternative in terms of a particular criterion, that may be used to distinguish between decision alternatives in terms of this criterion.

- *Objective*

A statement of preference in terms of an attribute, typically expressed as maximization or minimization of the numerical value of the attribute.

- *Goal*

A specific numerical value for an attribute that is deemed to represent a satisfactory level of performance in terms of the associated criterion.

For example, transportation safety may be identified as an important criterion in comparing hazardous waste disposal alternatives. An appropriate attribute might be road distance within urban areas over which material is to be transported. The associated objective would be minimization of this distance, while an associated goal may be to restrict this distance to not more than 50 km.

In the next section, we consider the process of eliciting the criteria relevant to a particular decision context by interaction with decision makers and/or other stakeholders (*see Stakeholder Participation in Risk Management Decision Making*), after which we turn to the practicalities of constructing an operationally meaningful *value tree* of attributes for purposes of decision aid and support. In the final section, we discuss the manner in which conflicting views of different stakeholder groups need to be taken into consideration.

Identification of Criteria

By definition, a criterion is a representation of human judgment regarding an issue that is important in a decision making context. Elicitation of criteria is therefore not a process of identifying a preexisting reality as is research in the natural sciences; it is a constructive process of problem structuring. A comprehensive review of problem-structuring methods is provided by Rosenhead and Mingers [4], while practicalities of facilitating the associated decision processes are discussed by Papamichail *et al.* [5].

The problem-structuring approaches discussed in the cited references have broader aims, but many have direct relevance to the identification of criteria. We have, in particular, found mind mapping concepts (e.g., the cognitive mapping of Eden and Ackermann [6], or the causal mapping described in Montibeller and Belton [7]) to be useful in eliciting criteria. This approach is illustrated in Figure 1, which displays such a map that was developed as a summary of concerns expressed by one fisher community during an investigation into the evaluation of fishing rights allocations in the Western Cape province of the Republic of South Africa (discussed by Stewart *et al.* [8]). The map connects a number of concepts by directed arcs, indicating the effects or influences of one concept on another. Concepts having incoming but no outgoing arcs are indicative of more-or-less

Figure 1 Illustrative causal map for identification of fundamental criteria

fundamental criteria of importance to the group. In the case illustrated in Figure 1, these criteria can be identified as health and nutrition status of the community (concept 107), social integration of the community (concept 106), crime (concept 105), and preservation of fishing stocks (concept 120). These criteria represent issues of concern to one stakeholder group, and the same process had to be repeated with other groups, and with the management of relevant government department, before a complete set of criteria could be identified.

In guiding the process of identifying criteria, the facilitator may find it useful to distinguish between what Keeney [9] terms fundamental and means-ends objectives (where in our terminology, his “objectives” correspond to our criteria and attributes). In this sense, “fundamental” refers to ultimate aims and purposes, while “means-ends” refers to more immediate objectives or goals (in the sense we have defined above) that can lead to attaining these ultimate aims or purposes. Such considerations lead to two distinct approaches to the elicitation of criteria as follows:

- *Top-down*

Start by identifying the fundamental criteria, often linked to broad concerns such as economic, social, and environmental issues. These need then to be broken down into more operational means of achieving the desired ends, until ultimately a clear set of measures of performance or achievement (the “attributes”) emerge.

- *Bottom-up*

Identify those characteristics (“attributes”) which differentiate between the available courses of action, and then consider their value relevance to fundamental aims or ends.

The facilitator may well alternate between the two approaches in working with decision makers or other stakeholders to construct a relevant set of criteria. Both approaches lead naturally to a hierarchical structure of criteria, sometimes termed the *value tree*, with an overall statement of ultimate intent at the root, progressively broken down into attribute measures against which decision alternatives can be evaluated

Figure 2 Value tree extracted from the causal map of Figure 1

and compared. A simple value tree extracted from the causal map of Figure 1 is illustrated in Figure 2; other examples may be found *inter alia* in Keeney [9]. The construction of such value trees is considered further in the next section.

Constructing the Value Tree

The problem-structuring process of the previous section typically requires the exercise of group value judgments by a number of decision makers and stakeholders, and thus often results in the tabling of a large number of issues, not all equally well defined operationally. For purposes of practical aid to decision making, further structure is then necessary to ensure that the resultant decision making process is both coherent and transparent. The use of a hierarchical value tree as mentioned above provides a format for clear and transparent structure that may easily be communicated between all role players. However, the criteria included in the tree, and especially the attributes at the detailed level, need to be subject to critical and careful scrutiny. The following (taken from Belton and Stewart [3], which is an expansion of an earlier list suggested by Keeney and Raiffa [2]), constitutes a useful checklist of aspects of the chosen set of criteria that need to be considered in constructing the final value tree of attributes on which decision making is to be based.

1. Value relevance

Are stakeholders able to express objectives or goals directly in terms of each attribute? Can they meaningfully state which of two decision alternatives

are preferred in terms of the associated criterion by consideration of this attribute alone (all other things assumed equal at this stage)?

2. Understandability

Do stakeholders share a common understanding of what is being measured by each attribute?

3. Measurability

Can the measure of performance of alternatives defined by the attribute be applied in a consistent manner? For example, it is well known that different people will apply a 1–5 scale in widely differing ways, unless the meaning of each point on the scale is very carefully defined, preferably with reference to external objective standards.

4. Operationally feasible

Can performance measures of alternatives in terms of each attribute be obtained or estimated with reasonable expenditure of effort, i.e., not placing excessive demands on decision makers and/or their staff.

5. Judgmental independence

Is it possible to think about trade-offs between performance on any two attributes, all other things being equal, without having to know the levels of achievement on the other attributes?

6. Nonredundancy

Do more than one attribute address essentially the same concerns, perhaps in different words or as subcriteria of different branches of the value tree (for example, employment as a component of both social and economic criteria)?

7. Balancing completeness and conciseness

The value tree should be complete, i.e., all important aspects of the problem should be captured, but should also be concise, keeping the level of detail to the minimum required.

8. Balancing simplicity and complexity

One should strive for the simplest value tree that adequately captures the essence of the decision making problem, i.e., is “requisite” in the sense defined by Phillips [10].

In some situations, there is a natural link from the criterion to a quantitative attribute. For example, in selecting between competing industrial processes,

one criterion might relate to levels of air pollution generated, which would naturally be measured in terms of concentrations of a specific set of contaminants or pollutants. Such measures would then represent the *natural attributes* at the lowest (most detailed) level of the value tree. Typically, a natural attribute creates little problem in terms of the first four aspects listed above. The attributes are, by definition, directly measurable and linked to the values of stakeholders, and are usually easily understood. In many cases, values for natural attributes are also readily available without excessive effort.

The first four aspects listed above demand greater care in the precise operational definition of the attributes when the associated criteria or objectives are of a more qualitative nature. Two approaches may then commonly be found:

- *Proxy attribute(s)*

Although there may not be a direct quantitative measure available, it may be possible to identify one of more related measures of performance that may serve as a proxy for the criterion. Belton and Stewart [3, Section 5.2], in an example of choosing the city in which to locate a new office, suggest a criterion of “availability of staff”. Such a criterion encompasses a broad range of concerns about both the range of skills available in the region, and the relationships between supply and demand in certain skills categories. It was then suggested that one surrogate or proxy measure may be the average number of applicants per advertisement placed for a particular category of post. Such an attribute cannot capture the full richness of concerns implied by the criterion, but may plausibly be correlated with many of these concerns.

Use of a proxy attribute (or a few such proxies at the lowest level of the value tree) may certainly be more operationally feasible than a complete exploration of issues, but care is necessary to ensure that the selected attribute has clear value relevance to stakeholders and decision makers.

- *Subjectively constructed attributes*

An alternative to seeking proxy attributes may be to construct a scale, by setting up verbal descriptions or reference scenarios of what would constitute different levels of performance in terms of the underlying criterion. Typically, some three to five levels are defined. Eventually, alternative policies or courses of action will then be evaluated by determining which

of the constructed scenarios most closely describes the alternative under consideration.

Belton and Stewart [3] also provide an example of a constructed scale for a “quality of life” criterion. A number of factors are identified, such as climate, pollution, safety, and cultural life, such that for each factor, any alternative location can be described as favorable, acceptable, or unfavorable. Three reference scenarios may then be defined:

- all factors are favorable.
- all factors are at least acceptable, with at most one unfavorable factor, if this is compensated by at least one favorable factor.
- there are no favorable factors, while three or more factors are unfavorable.

Two intermediate descriptions might also be provided to create a 5-point scale.

Constructed scales are more demanding in time and effort to ensure a broad level of understandability, but can be made highly value relevant.

The issue of judgmental independence (aspect 5, above) is not equally critical of all methods of multicriteria decision analysis. Nevertheless, for ease of understanding of the process, it is generally advantageous to be able to think about the importance of achieving specific levels of performance on one attribute without needing to modify such value judgments in the light of performance on other attributes. Keeney [11] has demonstrated how a redefinition of attributes can lead to greater levels preferential independence, so that judgmental independence may often be a matter of how attributes are defined (rather than a fundamental property of the problem context).

Consideration of the final three aspects listed above is a matter of judgment as to what detail of modeling is necessary for the problem at hand. Is the decision problem of sufficient importance to warrant additional effort? Are there outstanding issues that could substantially change conclusions reached?

Figure 3 is adapted from Belton and Stewart [3, page 81], and provides a more comprehensive illustration of a value tree which may finally emerge in a particular problem setting. The example was based on an earlier study by Stewart and Joubert [12] of a problem involving regional land use planning. The overall fundamental criterion was that of improving quality of life in the region; this criterion was subdivided into more fundamental concerns with social, economic, and environmental benefits. The third level represents

Figure 3 Illustrative value tree for regional water resources planning

more operational means to achieve the stated ends, most of which can be viewed as attributes except for “river status” which still needed to be further unpacked into the more specific attributes shown. All attributes are at this stage quantitative, although some may be viewed as proxies, for example, the number of ecotypes conserved as a proxy for biodiversity, and the two river flow measures as proxies for broader concerns with maintaining hydrological patterns.

Multiple Stakeholders

Multicriteria decision problems often arise because of the existence of a number of different interest groups. In much of the preceding discussion we have made reference to *decision makers* and *stakeholders*. In doing so, we have recognized the following characteristics of complex decision making problems:

- *Group decision making*

Corporate decisions are seldom made by an individual decision maker. The decision making process tends to be one of seeking consensus between different groups, and the techniques of MCDA are designed especially for this purpose.

- *External stakeholder or interest groups*

In addition to the previous point, there often exist a number of lobbies or pressure groups who do

not have direct responsibility for decision making, but who will attempt to influence decisions and/or take legal action to prevent unfavorable (to them) decisions from being implemented. Decision makers may well wish to consult with such groups in order, either to preempt later action or (at very least) to demonstrate that divergent interests have been taken into account.

The existence of interest and stakeholder groups does complicate the process of multiattribute modeling. Ideally, one might like to capture the concerns of all such groups in the value tree used for decision analysis. Unfortunately, this becomes operationally infeasible in some instances, as the value tree of attributes may become too large and detailed to allow for meaningful analysis. In such cases, it may be advisable to construct different value trees for different groups, for each to explore their own values and preferences, and to act as a medium of communication between groups.

Multiatribute Utility Functions

General Principles and Assumptions

A *multiatribute utility function* (MAUF) is a simple mechanism for evaluating decision alternatives in the context of a *multicriteria decision making* (MCDM) problem when outcomes are subject to risk or uncertainty, in other words, the consequences of any action are *random variables*. It is assumed that the MCDM problem itself has been formulated and structured in multiatribute terms (*see Multiatribute Modeling*), and that the resulting attribute measures are fully quantified in a cardinal sense (i.e., defined on a scale such that averaging is a meaningful operation). The MAUF can then be viewed as an integration of two concepts:

- the von Neumann–Morgenstern utility function for representation of risk preferences (*see Risk Attitude*); and
- a *multiatribute value function* (MAVF) (*see Multiatribute Value Functions*), extended to ensure that the output represents a strength of preference, rather than simply an ordinal rank.

We assume now that the outcomes consequent upon the choice of a specific decision alternative (course of action) may be represented in terms of a multivariate probability distribution of the relevant attribute values. We shall adopt the following notational conventions:

- Z_i^a : The performance of an alternative a in terms of attribute i (for $i = 1, 2, \dots, m$), viewed as a random variable whose distribution depends on the chosen alternative a .
- $\mathbf{Z}^a$: The vector of random variables $Z_1^a, Z_2^a, \dots, Z_m^a$.
- $z_i^a, \mathbf{z}^a$: Specific realizations of the random variables Z_i^a and $\mathbf{Z}^a$.

Without loss of generality, we may suppose that the attributes are defined such that increasing values are always preferred. The superscripts on $Z_i^a, \mathbf{Z}^a, z_i^a$, and $\mathbf{z}^a$ may be omitted when an undefined alternative is under consideration.

The function $U(\mathbf{z})$ is an *MAUF* representing decision maker preferences if it satisfies the property that alternative a is preferred to alternative b if and only if $E[U(\mathbf{Z}^a)] \geq E[U(\mathbf{Z}^b)]$, where expectation is taken with respect to the respective multivariate distributions on $\mathbf{Z}$ implied by choice of alternatives a or b .

The questions to be addressed in this article are the appropriate choice of functional form for $U(\mathbf{z})$, and the process of eliciting parameter values within this function to represent decision maker preferences. The development of the associated multiatribute utility theory is well documented in the classic texts of Keeney and Raiffa [1] and von Winterfeldt and Edwards [2], while a practitioner-oriented summary is provided in [3].

In the next section, we examine the implications and limitations of assuming a simple additive function for $U(\mathbf{z})$. Thereafter, we consider some relaxed assumptions concerning multivariate risk preferences, and identify the forms of function that arise then. In the final two sections, we give attention to elicitation of parameter values and comment on the ranges of practical applications of the MAUF model.

Assumptions and Implications of Additive Utility Functions

In the article *Multiatribute Value Functions*, it was noted that an additive functional form could be justified on the basis of relatively weak assumptions concerning preference structures. With this result in mind, it is tempting to attempt to represent $U(\mathbf{z})$ also in additive form, i.e., to assume that $U(\mathbf{z})$ can be expressed as

$$U(\mathbf{z}) = \sum_{i=1}^m k_i u_i(z_i) \quad (1)$$

where the k_i are some form of weights, and the $u_i(z_i)$ are marginal (single attribute) utility functions.

Clearly, the $u_i(z_i)$ must be one-dimensional utility functions in the von Neumann–Morgenstern sense (see [3], for example). This assertion follows directly by considering alternatives that have identical fixed (deterministic) values on all attributes except attribute, say, i . With the assumption of the additive utility, an alternative a is preferred to an alternative b if and only if $E[u_i(Z_i^a)] \geq E[u_i(Z_i^b)]$.

In terms of the additive model, the evaluation of $E[U(\mathbf{Z})]$ depends only on the marginal probability distributions of the components of $\mathbf{Z}$, and not on any properties of their joint distributions. The additive model is thus only justifiable if decision maker preferences depend only on the marginal distributions, a property that is termed *additive independence*. In order to understand the restrictions implicit in the assumption of additive independence, consider the two-dimensional case, i.e., $m = 2$, with only two possible outcomes on each criterion, which we shall denote by $z_i^0 < z_i^1$ for $i = 1, 2$. Without loss of generality, we may then standardize the marginal utility functions such that $u_1(z_1^0) = u_2(z_2^0) = 0$ and $u_1(z_1^1) = u_2(z_2^1) = 1$. Now suppose that the two alternatives a and b generate outcomes as follows:

- *alternative a* results in one or other of the two outcomes $(z_1^0; z_2^0)$ and $(z_1^1; z_2^1)$, with equal probabilities on each; while
- *alternative b* results in one or other of the two outcomes $(z_1^0; z_2^1)$ and $(z_1^1; z_2^0)$, with equal probabilities on each.

The additive model results in an expected utility of $(k_1 + k_2)/2$ for both alternatives, implying that the decision maker should be indifferent between a and b irrespective of the specific details. Such indifference, however, may well be violated because of the following reasons:

- In some cases, the values on the two attributes may be compensatory, so that alternative b , which guarantees some gain over the worst case may well be preferred by a risk averse decision maker to alternative a .
- In other contexts, the attributes may refer to gains to different stakeholders. Under such circumstances, decision makers may prefer alternative a , which avoids the inevitable conflict that would arise when there is always one winner and one loser.

The additive model (1) may thus represent too strong an assumption in many cases. Although it has been demonstrated (e.g., Stewart [4]) that the effect of the additive assumption may be small in comparison to other errors and biases, such as in the assessment of the marginal utilities $u_i(z_i)$, models arising from less restrictive assumptions may be more defensible. These are discussed in the next two sections.

Utility Independence and Multiplicative Aggregation

In order to weaken the assumption of additive independence, we need to introduce the concept of *utility independence*. Suppose that we partition the set of attributes into two disjoint subsets, say $\mathbf{Z} = (\mathbf{Y}, \bar{\mathbf{Y}})$, where $\mathbf{Y}$ is a vector of $p < m$ attributes, and $\bar{\mathbf{Y}}$ is the complement of $\mathbf{Y}$, i.e., the elements of $\mathbf{Z}$ not included in $\mathbf{Y}$. We say that the subset of attributes $\mathbf{Y}$ is *utility independent* of its complement if the decision maker's preferences between probability distributions on $\mathbf{Y}$, given that outcomes on $\bar{\mathbf{Y}}$ are deterministically fixed, do not depend on these fixed values.

The attributes in $\mathbf{Z}$ are said to be *mutually utility independent* if every subset of the attributes in $\mathbf{Z}$ is utility independent of its complement. Note that this condition implies *inter alia* that preferences for gambles on any one attribute, say Z_i , given that all other attributes are fixed, do not depend on these fixed levels for the other attributes. It is then still operationally meaningful to establish a marginal utility function $u(z_i)$ for each attribute in the standard manner.

If the attributes in a given decision problem are mutually utility independent, then it can be shown (see for example Keeney and Raiffa [1], Section 6.3) that the aggregate utility function $U(\mathbf{z})$ is functionally related to the marginal utility functions $u_i(z_i)$ in multiplicative form defined by

$$1 + kU(\mathbf{z}) = \prod_{i=1}^m [1 + kk_i u_i(z_i)] \quad (2)$$

where the parameter k is related to the relative importance parameters k_i through

$$1 + k = \prod_{i=1}^m [1 + kk_i] \quad (3)$$

It may be confirmed that $-1 < k < \infty$ when $k_1 = k_2 = \dots = k_m$. Furthermore, the solution with $k = 0$ reduces to the additive model (1) with $\sum_{i=1}^m k_i = 1$, so equation (1) is just a special case of equation (2).

In the two-attribute example of the previous section, the expected utility based on equation (2) can be calculated to be $(k_1 + k_2 + kk_1 k_2)/2$ for alternative a , but $(k_1 + k_2)/2$ for alternative b . The multiplicative model thus no longer forces an equivalence between alternatives a and b , since a is preferred to

b for $k > 0$, but *vice versa* for $k < 0$. In this sense, the parameter k is seen to be a measure of preference for more equitable outcomes (as opposed to compensation between criteria).

Weaker Forms of Independence Assumptions

The multiplicative model arising from the assumption of mutual utility independence allows for modeling a wide range of preference structures over multiattribute outcomes under uncertainty in a relatively simple manner, requiring only the need to elicit the marginal utility functions and the m scaling parameters k_i (see section titled “Practical Application”). Nevertheless, the assumption of mutual utility independence may be quite difficult to validate fully in practice, so that it may be desirable to seek less restrictive assumptions.

If we expand both sides of equation (2) then we obtain an equivalent expression for $U(\mathbf{z})$ as follows:

$$\begin{aligned} U(\mathbf{z}) = & \sum_{i=1}^m k_i u_i(z_i) + k \sum_{i=1}^{m-1} \sum_{j=i+1}^m k_i k_j u_i(z_i) u_j(z_j) \\ & + k^2 \sum_{i=1}^{m-2} \sum_{j=i+1}^{m-1} \sum_{\ell=j+1}^m k_i k_j k_\ell u_i(z_i) u_j(z_j) u_\ell(z_\ell) \\ & + \cdots + k^{m-1} \prod_{i=1}^m k_i u_i(z_i) \end{aligned} \quad (4)$$

Clearly equation (4) is a special case of the following multilinear aggregation function:

$$\begin{aligned} U(\mathbf{z}) = & \sum_{i=1}^m k_i u_i(z_i) + \sum_{i=1}^{m-1} \sum_{j=i+1}^m k_{ij} u_i(z_i) u_j(z_j) \\ & + \sum_{i=1}^{m-2} \sum_{j=i+1}^{m-1} \sum_{\ell=j+1}^m k_{ij\ell} u_i(z_i) u_j(z_j) u_\ell(z_\ell) \\ & + \cdots + k_{12\dots m} \prod_{i=1}^m u_i(z_i) \end{aligned} \quad (5)$$

in which independent weighting factors apply to every cross product term.

In fact, for the case of $m = 2$ there is no real difference between the multiplicative and multilinear

models (the only difference being a replacement of the parameter k by $k_{12} = k k_1 k_2$). However, for $m > 2$, the models diverge, and equation (5) becomes a nontrivial extension of equation (2).

It has been shown (Keeney and Raiffa [1], Section 6.3) that a set of assumptions that are weaker than mutual utility independence are sufficient to demonstrate the validity of the more general aggregation rule given by equation (5). The required assumption is only that each individual attribute Z_i be utility independent of its complement (i.e., of all attributes except the i th). Since the utility independence of each Z_i from its complement is in any case necessary in order to construct the marginal utility functions, this assumption is about the weakest that can be made in order to form an aggregate multiattribute utility, so that equation (5) is in effect the most general model that we can find for our purposes.

Unfortunately, however, the number of parameters that need to be elicited from decision makers in order to construct the multilinear model grows rather rapidly. For the multiplicative model, we require the elicitation of precisely m parameters. For the multilinear model, however, a total of $2^m - 1$ scaling parameters are needed (giving, for example, 31 parameters when $m = 5$). These numbers rapidly become practically unmanageable (see next section).

Practical Application

The first step in the elicitation of any MAUF (whether additive, multiplicative, or multilinear) is the assessment of the marginal (single attribute) utility functions $u_i(z_i)$. This requires the same procedures as described in the article **Risk Attitude**, applied independently to each attribute.

In the case of the additive model, the weights k_i can be determined by direct consideration of deterministic trade-offs, essentially as described in the article **Multiattribute Value Functions**.

For the multiplicative model, the *relative* magnitudes of the k_i can also be assessed as for deterministic MAVFs. However, in order to determine the appropriate value for k (or, equivalently, the scaling to be applied to the k_i), it is necessary to elicit preferences between multivariate lotteries. In order to illustrate this last elicitation step, suppose that the relative weights have been established (as in the deterministic case), and standardized to give weights

$w_1, \dots, w_m$ such that $\sum_{i=1}^m w_i = 1$. It then follows that $k_i = \alpha w_i$ for some as yet unknown scaling factor α , giving $\sum_{i=1}^m k_i = \alpha$.

One approach might then be to select two attributes (which with no loss of generality can be assumed to be the first two), and to present the decision maker with a choice between two hypothetical alternatives that have identical and deterministic outcomes on attributes $3, \dots, m$, but which have uncertain outcomes on attributes 1 and 2 specified as follows (using the same definitions of z_i^0 and z_i^1 as in the earlier example, i.e., such that $u_i(z_i^0) = 0$ and $u_i(z_i^1) = 1$ for $i = 1, 2$):

- *alternative a* results in the outcome $(z_1^1; z_2^1)$ with probability p , and in the outcome $(z_1^0; z_2^0)$ with probability $1 - p$; while
- *alternative b* results in one or other of the two outcomes $(z_1^0; z_2^1)$ and $(z_1^1; z_2^0)$, with equal probabilities on each.

In this hypothetical case, the decision maker would be asked to specify the probability p that would make him/her indifferent between the two alternatives. Simple algebraic manipulation confirms that the parameters of the multiplicative model must then satisfy the following:

$$\begin{aligned} & \frac{1}{2} (1 + kk_1) + \frac{1}{2} (1 + kk_2) \\ &= p (1 + kk_1) (1 + kk_2) + 1 - p \end{aligned} \quad (6)$$

Now define $c = \alpha k$. The above equality simplifies to

$$\frac{c}{2} (w_1 + w_2) = pc (w_1 + w_2) + pc^2 w_1 w_2 \quad (7)$$

for which the only solutions are $c = 0$ or

$$c = \frac{(0.5 - p)(w_1 + w_2)}{pw_1 w_2} \quad (8)$$

Since $c = 0$ implies $k = 0$, the zero solution is only valid if the additive model applies, in which case (as we have previously seen) we must have $p = 1/2$. Thus for $p \neq 0.5$ the only solution is given by equation 8. Finally, the value k will be obtained from

$$1 + k = \prod_{i=1}^m (1 + cw_i) \quad (9)$$

Table 1 Multiattribute risk parameters as function of assessed probabilities

p	c	k
0.3	2.667	4.444
0.4	1.000	1.250
0.5	0.000	0.000

Table 2 Marginal utilities for different values of two attributes

Level	Cost		Time	
	\$ m	Utility	Mins	Utility
z_i^0	25	0	30	0
z_i^1	20	0.7	22.5	0.4
z_i^2	15	1	15	1

Illustrative Numerical Values

For the case of $m = 2$ and $w_1 = w_2$, the Table 1 indicates the values of k corresponding to a few sample values of p .

Numerical Example

We return to the example of choosing between alternative routes for a highway introduced in the article **Multiattribute Value Functions**. This example involved only two attributes, namely total investment cost (\$ million) and mean transit time (min). Suppose now that for any alternative there are only three possible outcomes, namely \$15, \$20, and \$25 million for investment cost and 15, 22.5, and 30 min for transit time, but that alternatives differ in terms of the probabilities on each of the nine possible outcomes.

Without loss of generality, utilities of 0 and 1 can be associated with the worst and best outcomes on each criterion, respectively. The marginal utility functions will thus be fully defined by assessing the relative utilities for the intermediate values on each criterion. For purposes of illustration, suppose that the marginal utilities for each attribute have been assessed as shown in Table 2 (by consideration of gambles, as discussed in the article **Risk Attitude**).

Finally, suppose that equal weights are associated with each criterion (i.e., $k_1 = k_2$).

For this simple case with $m = 2$ and $k_1 = k_2$ (i.e., $w_1 = w_2$), it is easily confirmed that equations (8) and (9) lead to $c = 2(1 - 2p)/p$, $k = c(1 + c/4)$, and $k_1 = k_2 = p$.

Consider now three alternative routes with (stochastic) outcomes described as follows:

- A. This option results in (cost = \$25 million, time = 30 min) with probability $1/8$; (cost = \$25 million, time = 22.5 min) with probability $1/8$; and (cost = \$15 million, time = 22.5 min) with probability $3/4$. The expected utility then becomes $1.1p + 0.3p^2$.
- B. This option results in two possible outcomes occurring with equal probabilities, namely (cost = \$25 million, time = 30 min) and (cost = \$15 million, time = 15 min). The expected utility is then 0.5 for any value of p (or k).
- C. This option results in the certain outcome (cost = \$25 million, cost = 15 min), which has (expected) utility of $k_2 = p$.

Table 3 gives the expected utilities for the three options for three different values of p and the associated k .

This example thus demonstrates that each of the three options can in principle be optimal, depending on the level of the decision maker's multivariate risk aversion measured by k .

Conclusions

Although the simple example of the previous section illustrates the potential for the parameter k to

substantially influence recommendations from the model, it should be evident that questions regarding preferences between multivariate lotteries is cognitively much more difficult than for univariate lotteries. The analyst would thus be advised to repeat the exercise for a number of different combinations of attributions and levels, as a check on consistency. Such an approach, however, places additional cognitive burdens on the decision maker.

The situation with the multilinear linear model is even more difficult. A minimum of $2^m - m$ comparisons between multivariate lotteries would be needed in order to assess all the parameters in equation (5), but in fact many more would be needed for purposes of consistency checks.

The complexity of the questions that need to be answered in order to elicit the parameters of multiplicative or (even worse) multilinear models means that many reported applications of MAUFs have been restricted to the additive model. Fortunately, simulation studies (e.g., Stewart [4]) have revealed that in many instances the sensitivity of results to departures from additivity are substantially smaller than sensitivity to other errors, such as in the assessment of the marginal utilities $u_i(z_i)$. Nevertheless, the analyst should be aware of the potential for biases arising from use of the additive model when undertaking sensitivity analyses.

Multiatribute Value Functions

General Principles and Assumptions

A *multiatribute value function (MAVF)* is a simple mechanism for evaluating decision alternatives in the context of a *multicriteria decision making (MCDM)* problem. The MAVF is a special case of a value function (see **Value Function**), arising when the MCDM problem is formulated and structured in multiatribute terms (see **Multiatribute Modeling**).

The process of multiatribute modeling leads to a representation of decision alternatives in terms of performance measured on each of a number of identified and quantified *attributes* (although some attributes may be measured on a subjectively constructed scale). The assumption is that preferences between alternatives can, for purposes of practical decision making, be expressed entirely in terms of the associated attribute values. We adopt the following notational conventions:

$a, b, \dots$:	decision alternatives which are to be compared and/or evaluated;
$z_i(a)$:	performance of alternative a as measured on attribute i , for $i = 1, 2, \dots, m$;
z_i :	an arbitrary measure of performance in terms of attribute i ;
$\mathbf{z}, \mathbf{z}(a)$:	the m -dimensional vectors with elements z_i and $z_i(a)$ respectively.

Without loss of generality, we may suppose that the attributes are defined such that increasing values are always preferred, i.e., the alternative a is preferred to b in terms of attribute i if and only if $z_i(a) > z_i(b)$.

For most of this article, we assume that there are a finite number of alternatives, but some generalizations are discussed in the section titled “Mathematical Programming Structures”.

In principle, a *value function* $V(a)$ defined on the alternatives is such that the alternative a is preferred to alternative b ($a \succ b$) if and only if $V(a) > V(b)$. In some cases, stronger properties than simple preservation of preference order (e.g., representation of strength of preference) may be required of the value function. For purposes of the present article, it is sufficient (except in the section titled “Generalized Functional Forms”) to restrict

discussion to the simplest assumption of preservation of preference order only.

The basis of multiatribute modeling is that an alternative a may be represented fully by the associated vector of attribute values $\mathbf{z}(a)$, so that $V(a)$ can be expressed as $V[\mathbf{z}(a)]$. For this reason, the MAVF approach is to construct a function of the attribute values directly, say $V(\mathbf{z})$, which may then subsequently be applied to the specific alternatives $a, b, \dots$. The process of constructing $V(\mathbf{z})$ involves the following two distinct stages:

- construction of, what we term, *partial value functions* $v_i(z_i)$ for each attribute: by the assumption made about the direction of preference on attributes, $v_i(z_i)$ must be a monotone strictly increasing function of its argument, but we shall see that there are additional properties that need to be satisfied.
- aggregation of the partial value functions into the complete value function $V(\mathbf{z})$.

Detailed discussions of the principles underlying MAVFs may, for example, be found in Keeney and Raiffa [1] or in von Winterfeldt and Edwards [2].

In the next section, we investigate conditions under which the aggregation step is of a simple additive form. It turns out that these conditions are relatively mild, and lead to very simple and transparent processes for decision analysis. In the following section, we also describe the methods by which the components of the value function can be elicited from decision makers or other stakeholders. We then discuss a number of extensions to the basic value function model, taking into consideration mathematical programming decision structures, stronger value function properties leading to nonadditive forms, and the use of the attribute structure to deal with risk and/or time preferences.

Additive Value Functions

We consider now a simple additive aggregation, i.e., construction of an overall value function in the form

$$V(\mathbf{z}) = \sum_{i=1}^m w_i v_i(z_i) \quad (1)$$

where the parameters w_i indicate a form of importance weight on the criterion represented by attribute

i. The appeal of the model given by equation (1) is in its simplicity, which makes the processing transparent to decision makers and other stakeholders. The question may, nonetheless, arise as to whether the model is not too simplistic and reductionistic, perhaps invoking unrealistic assumptions. Surprisingly, however, the additive form is a legitimate order-preserving value function, provided that some care and discipline is exercised in selecting the attributes, defining the functions $v_i(z_i)$, and specifying the weights. Two critical issues relate to *preferential independence* of the attributes and to a required *interval scale property* of the partial value functions. Both issues can be understood in terms of simple algebraic properties of equation (1), as discussed in the next two subsections.

Preferential Independence

Suppose that two alternatives a and b differ on r attributes only, where $1 < r < m$. Let $\mathcal{D}$ be the set of attributes on which the two alternatives differ. Since, by definition, $z_i(a) = z_i(b)$ for $i \notin \mathcal{D}$, it follows that a is preferred to b if and only if

$$\sum_{i \in \mathcal{D}} w_i v_i(z_i(a)) > \sum_{i \in \mathcal{D}} w_i v_i(z_i(b)) \quad (2)$$

irrespective of the performances of these two alternatives in terms of attributes not in $\mathcal{D}$ (i.e., on which their performances are identical). It thus follows that for an additive aggregation to apply, the decision maker must be able to express meaningful trade-offs between levels of achievement on the attributes in $\mathcal{D}$, assuming that levels of achievement on the other attributes are fixed, *without* needing to be concerned with what these fixed levels of achievement are. This is the property that we term *preferential independence*, and which is a stronger form of judgmental independence alluded to in the article on multiattribute modeling.

Example 1: Suppose that three attributes relevant to choice of a water development scheme in an arid region are identified as investment cost (from taxpayers' money), person-days of access to recreational facilities, and number of invertebrate species conserved. From a political viewpoint, it may be much more difficult to justify restrictions on recreational access to achieve higher numbers of invertebrate species conserved if investment costs have been high

(i.e., high demands on taxpayers) than if these costs are low. If this is true, then person-days of access to recreational facilities and number of invertebrate species are not preferentially independent of investment cost. Some reformulation will be necessary to justify use of an additive value function model (perhaps as discussed in Keeney [3]).

The preferential independence condition amongst the attributes is thus a *necessary* condition for an additive value function (1) to be valid; in fact this condition, together with some technical assumptions regarding continuity, transitivity, and completeness of preferences, are in fact *sufficient* to prove the existence of an additive value function, i.e., there will always exist an additive model on a set of attributes satisfying preferential independence (see Keeney and Raiffa [1, Chapter 3], for a proof). Before proceeding with the use of an additive value function modeling approach in multicriteria decision analysis (MCDA), therefore, it is necessary to confirm that the criteria and associated attributes are so defined that the decision maker's values are preferentially independent amongst the modeled attributes. In the event of serious doubt about the validity of these assumptions, one should return to the structuring process.

It is perhaps important, at this stage, to differentiate between the concept of preferential dependence, and that of structural or statistical dependence between performance levels for different attributes. It may well happen that the structure of the decision space is such that improved performance in terms of one attribute is strongly associated with poor performance in terms of another. This does not, in any way, preclude the possibility that the decision maker's preferences may still satisfy the preferential independence properties.

Interval Scale Property

We have noted that the partial value functions $v_i(z_i)$ are monotone increasing in the attribute values z_i , but we have not yet otherwise specified the functional form. The preferential independence property is sufficient to show that *some* additive value function exists, but this does not imply that the additive aggregation applies to *any* arbitrary set of increasing functions $v_i(z_i)$.

It is clear that the addition or subtraction of a constant term to each of the $v_i(z_i)$ does not affect the

preference ordering implied by the resultant $V(\mathbf{z}(a))$. The addition of such a constant term simply redefines the (generally arbitrary) level of performance that is allocated a “zero value” so as to provide a reference point against which other performances are measured. Ratios of partial values will accordingly not be meaningful, in general (since addition of constants to each $v_i(z_i)$ will change their ratios), except in special circumstances under which a natural and unambiguous zero value point exists, which would preclude such addition or subtraction of constant terms. Consequently, only ratios of *differences* between the $v_i(a)$ (i.e., the relative magnitudes of differences) have any absolute meaning independent of the generally arbitrary choices of zero point and scaling. This is the defining property of an *interval scale* of preferences.

The implication of the interval scale property is best seen by looking again at trade-offs between performance levels for different attributes. For attribute i , consider two pairs of performance levels, say $z_i^1 > z_i^0$ and $z_i^3 > z_i^2$. Suppose that the corresponding value differences are equal, i.e., that $v_i(z_i^1) - v_i(z_i^0) = v_i(z_i^3) - v_i(z_i^2)$. Clearly, if an increase from z_i^0 to z_i^1 just compensates for specified losses in other attributes, then the increase from z_i^2 to z_i^3 will equally well just compensate for those same losses. In constructing the partial value functions, therefore, it is important to check that equal increments in $v_i(z_i)$ do indeed represent equal trade-offs against other attributes, i.e., that the property of *constant relative trade-offs* applies to comparisons between performance as measured on the value scales $v_i(z_i)$. These constant trade-offs are illustrated in the next example.

Example 2: Suppose that a choice needs to be made between alternative routes for a highway, and that just two attributes (criteria) have been identified: total investment cost and mean transit time. In this case, for both attributes, smaller values are preferred to larger values, so that we might formally define the algebraic attributes, for example, by

$$z_1 = 25 - \text{Investment cost in millions of dollars} \quad (3)$$

$$z_2 = 30 - \text{Transit time in minutes} \quad (4)$$

where the zero points are defined by the worst outcomes under consideration (\$25 M and 30 min). In

the next section, we look at the process of eliciting value functions, but for illustrative purposes suppose, for now, that we have established a partial value function for mean transit time as $v_2(z_2) = z_2^2$. It is easily confirmed that $v_2(9) - v_2(5) = 56$ (corresponding to transit times of 21 and 25 min respectively) and $v_2(15) - v_2(13) = 56$ (corresponding to transit times of 15 and 17 min respectively).

The implication is that whatever the value function for investment cost, if decision makers are prepared to accept an increase in investment cost from 20 to 21 million dollars (say) to reduce mean transit time from 25 to 21 min, then for any additive model to hold, they should equally well be prepared to accept an increase in investment cost from 20 to 21 million dollars to reduce mean transit time from 17 to 15 min. As the value functions are constructed, these implied trade-offs need regularly to be fed back to decision makers, to ensure that the functions do indeed (at least approximately) satisfy the interval scale property.

Elicitation of Additive Value Functions

In the previous section, we have seen that the additive value function model provided by equation (1) is simple, transparent, and yet broadly justifiable provided that certain assumptions are met. As the analyst constructs the model by eliciting the partial value functions and weights from clients (decision makers or other stakeholders), care needs to be exercised to ensure that the assumptions do hold, at least to a good level of approximation.

The process of elicitation involves two distinct steps, namely, elicitation of the individual partial value functions $v_i(z_i)$, followed by elicitation of the weights w_i . The first assumption to be verified is that of preferential independence, which can, in fact, be checked as part of both steps in the elicitation:

- In the process of constructing $v_i(z_i)$, can decision makers express judgments on the worth of different increments on the z_i scale without needing to think about performance levels on other attributes?
- In the process of estimating weights, can decision makers express trade-offs between subsets of attributes without needing to think about performance levels on other attributes?

If no serious difficulties are encountered, then we may safely assume that a satisfactory level of preferential independence exists. We now assume that this independence is satisfied as we move on the elicitation process itself.

Partial Value Functions

We require that $v_i(z_i)$ be an increasing function of z_i (recalling the assumed definition of the attribute in increasing preference terms). A further assumption which is frequently encountered in reported application of MAVFs is that a linear function can be used, i.e., $v_i(z_i) \approx az_i + b$. This is, in fact, the assumption that *constant relative trade-offs* apply to the immediately defined attributes z_i .

In constructing the partial value functions, the interval scale property needs to be verified, which may be done by systematic checks on whether constant relative trade-offs appear to hold. It has been our experience, however, that constant relative trade-offs between directly or naturally defined attributes (z_i) are perhaps the exception rather than the rule, so that the linear partial value function may typically not be valid. For example, in fisheries risk management, an important attribute is that of the population size of an endangered species. As an illustration, suppose that population sizes for one such species ranges from 0 to 5000. It might well be argued in a particular case that there is very little advantage gained (in terms of long-term survival of the species) in going from a population of 0 to say 1000. However, from that point onward, survivability is greatly enhanced by further population increases up to say 3500, at which point the species is quite safe. Clearly, therefore, increments in the population size from (say) 1500 to 2500 is much more important than either from 0 to 1000, or from 3500 to 4500. The natural attribute measurement does not then satisfy the interval scale property, and it is more likely that the sigmoidally shaped partial value function illustrated in Figure 1 will capture true value preferences (where the squares indicate points at which values may have been elicited, as discussed later).

It has been demonstrated by Stewart [4, 5] that the inappropriate assumption of linearity of the partial value function can be the major source of bias in applying MAVFs (tending to favor more extreme alternatives which are very good on some criteria and

Figure 1 Illustration of a nonlinear partial value function

very poor on others, over more moderate compromises). The same work, however, has demonstrated that it is usually sufficient to assess relative values at about five different performance levels, and to interpolate between these to define the complete functions. It is also common practice when constructing categorical scales, to keep to about five categories. Typically, therefore, the construction of the partial value function requires only that relative values be assessed for a relatively small number of performance levels, which for convenience we denote by $z_i^0, z_i^1, \dots, z_i^p$, say. We describe the process on the basis of a small number of performance levels defined in this way.

To facilitate the later interpretation of the weights w_i (next subsection), it is generally preferable to scale the partial values $v_i(z_i)$ in a consistent manner. For this purpose, it is important to identify the extremes of $z_i(a)$ which are under consideration, which may be specified in either of the following ways:

- “*locally*” as the best and worst outcomes observed in the range of alternatives under consideration or
- “*globally*” as the best and worst outcomes that are conceivably ever likely to present themselves, now or in the future.

Let z_i^* and z_i^0 be the best and worst performance levels identified in this way for criterion i . It is convenient to define the partial value functions such that $v_i(z_i^0) = 0$ for each i , while $v_i(z_i^*)$ is set at some fixed value, often 1, 10, or 100.

There are two approaches that may then be adopted in constructing the value functions:

- Select a set of performance levels $z_i^0, z_i^1, \dots, z_i^p$ (often evenly spaced), followed by an elicitation from the decision maker of the relative values or worth of the increments $z_i^r - z_i^{r-1}$ for $r = 1, 2, \dots, p$ (e.g., Watson and Buede [6]).
- Assuming that the worst-case performance (z_i^0) has been specified, select an arbitrary higher level of performance z_i^1 (at about 10–20% of the range up to z_i^*); then, for $r = 2, 3, \dots$ elicit from the decision maker, the performance level z_i^r such that the increments from z_i^{r-2} to z_i^{r-1} and from z_i^{r-1} to z_i^r are of equal value, and continue until z_i^* is exceeded (e.g., von Winterfeldt and Edwards [2]).

Example 3: We illustrate the two approaches by reference to the previous example of a fish population size.

First method:

We have $z_i^0 = 0$ and $z_i^* = 5000$. Suppose that four equally spaced intermediate levels were selected to give: $z_i^1 = 1000$, $z_i^2 = 2000$, $z_i^3 = 3000$, $z_i^4 = 4000$, and $z_i^5 = 5000$. The decision maker might first be asked which of the five increments represents the greatest importance or worth toward achievement of the underlying criterion. Suppose that the second interval (from 1000 to 2000) is identified. Thereafter, the relative worths of each of the other increments (relative to the second interval) in performance level might be elicited as shown in the second column of Table:

The incremental relative values are cumulated in the third column of Table 1, and provides values of a partial value function at the end points of each interval. As indicated above, it is useful to apply a consistent scaling. For example, to obtain a 0–100 value scale, the values in the last column may be divided by 2.45 to give $v_i(1000) = 14$,

Table 1 Value assessment by comparing equal increments

Range of performance levels	Relative value of increment	Cumulative relative value
0–1000	35	35
1000–2000	100	135
2000–3000	75	210
3000–4000	25	235
4000–5000	10	245

$v_i(2000) = 55$, $v_i(3000) = 86$, $v_i(4000) = 96$, and (by definition) $v_i(5000) = 100$. These are in fact the points plotted for the value function illustrated in Figure 1.

It is often useful when interacting with decision makers using this method, to display the values on a “thermometer scale” as illustrated in Figure 2. It is our experience that decision makers relate easily to shifting the end points along the scale to get a visual impression of the value gaps being proposed.

Second method:

Start with (say) a first interval between 0 and 1000 (20% of the range). The decision maker would be asked to suggest a value x , such that the value of an increment from 1000 to x is equivalent to that of an increment from 0 to 1000. Suppose that the answer is given as $x = 1400$. Further questions of the same form would elicit ranges such as those displayed in Table 2, all being of equal worth:

Figure 2 Illustration of a thermometer scale for value function elicitation

Table 2 Value assessment by identifying increments of equal worth

Increment		Unstandardized Cumulative value
From	To	
0	1000	1
1000	1400	2
1400	1750	3
1750	2100	4
2100	2500	5
2500	3200	6
3200	6500	7

The last column provides a relative “value” at the end points of each interval, which can be standardized as desired. There is no reason why the scale should not now be chosen to be 0–6500 even though no actual alternative reaches that far. Alternatively, an interpolation between 3200 and 6500 might be applied to give an approximate value on the unstandardized scale of about 6.5 at $z_i = 5000$. Rescaling to make $v_i(5000) = 100$ would then *pro rata* give $v_i(1000) = 15$, $v_i(1400) = 31$, $v_i(1750) = 46$, $v_i(2100) = 62$, $v_i(2500) = 77$, $v_i(3200) = 92$, and (again by definition) $v_i(5000) = 100$.

Weights

To complete the construction of the additive value function, we also need to elicit the appropriate weights w_i . It is important to recognize the algebraic meaning of the weight parameters, however. Let us suppose that we have scaled the partial value functions between the defined best and worst performance levels z_i^* and z_i^0 , so that $v_i(z_i^0) = 0$ and $v_i(z_i^*) = 100$ (say) for each attribute i . Consider now two hypothetical alternatives, a and b , that differ in terms of two attributes only, say i and j , and such that for alternative a $z_i(a) = z_i^*$, $z_j(a) = z_j^0$, while for alternative b $z_i(b) = z_i^0$, $z_j(b) = z_j^*$. It is clear then that $V(\mathbf{z}(a)) - V(\mathbf{z}(b)) = w_i - w_j$, so that a is preferred to b (implying that the “swing” from z_i^0 to z_i^* is worth more to the decision maker than the “swing” from z_j^0 to z_j^*) if and only if $w_i > w_j$. In this sense, the ratio w_i/w_j indicates the relative importance of these two “swings”.

The relative weights can also be understood in terms of trade-offs. In the example of the previous paragraph, suppose that $w_i > w_j$. Since the swing

from z_i^0 to z_i^* is worth more than the “swing” from z_j^0 to z_j^* , it should be possible to identify a smaller swing of values on attribute i that would compensate exactly for the full swing on attribute j . For example, decision makers may be asked to state a value $\hat{z}_i$ such that they are indifferent between the outcome pairs $\{\hat{z}_i(a); z_j^0\}$ and $\{z_i^0; z_j^*\}$ (again assuming equality on all other attributes). This defines a *trade-off* as the amount the decision maker would wish to gain on attribute i (i.e., $\hat{z}_i - z_i^0$), to compensate for the loss of going from z_j^* down to z_j^0 on attribute j . The indifference between the two pairs implies by the additive value function model that $w_i v_i(\hat{z}_i) + w_j \cdot 0 = w_i \cdot 0 + w_j \cdot 100$ or $w_j/w_i = v_i(\hat{z}_i)/100$.

In either interpretation, we note that it is only the weight ratios that are meaningful. The individual weights may be scaled arbitrarily, a common choice (which tends to facilitate interpretation) being to scale the weights so that $\sum_{i=1}^m w_i = 1$.

The critical observation to be made is that the algebraic meaning of weight ratios, interpreted either as swings or trade-offs, is defined by the range of attribute values under consideration. If this range is modified for one attribute, then the weight parameter must change accordingly. The implication is that weight ratios cannot meaningfully be assessed in absolute terms, independently of context. In eliciting weights, the analyst or modeler must ensure that the client (decision maker or stakeholder) takes the context into account when answering questions.

Practical means of eliciting weights in a manner consistent with the above principles are discussed in the cited references (e.g., [1, 2, 7]). It is generally convenient to have the decision maker consider not more than two to five attributes at a time. Different sets of attributes for evaluation are selected in such a way that any pair of attributes will be linked directly or indirectly through a sequence of comparisons.

Evaluation of relative weights within any one set of attributes might start with a simple ranking of the relative importance of the swings on each attribute. (For algebraic convenience, we have defined swings above by the full range from z_i^0 to z_i^* , but it is possible with appropriate algebraic manipulation to consider only portions of each range.) The following two possible approaches may then be available to the decision maker:

- to assess the relative worths of each swing or
- to specify pairwise trade-offs as defined above.

The second approach is in some senses the most precise, but decision makers are often resistant to specifying trade-offs, especially in politically sensitive areas, in which case the first approach may be found to be more acceptable.

Extensions

We conclude with brief mention of a number of extensions to the simple additive value function model as described above for discrete choice multicriteria decision problems with deterministic outcomes (i.e., no uncertainties).

Generalized Functional Forms

It is important to note that when we speak of preferential independence (together with the other technical assumptions) being sufficient to prove the *existence* of an additive value function, this result only applies to ordinal value functions, i.e., with the property that $a \succ b$ if and only if $V(a) > V(b)$. It is not necessarily true that stronger cardinal properties hold. For example, if for three alternatives $a \succ b \succ c$ we have $V(a) - V(b) > V(b) - V(c)$, it is not legitimate to claim that the strength of preference for a over b is greater than the strength of preference for b over c .

In many applications, the ordinal property is sufficient for decision making purposes. The main context in which relative strengths of preference become an important consideration is that of decision making under uncertainty or risk. Under such circumstances, each alternative is associated with a number of different possible outcomes, and it becomes necessary to consider the combined effects of many different possible trade-offs, for which some measure of strengths of preference for different possible trade-offs is required.

The extension of MAVF theory into *multiattribute utility theory* for purposes of dealing with MCDM under risk or uncertainty is discussed in a separate article. This theory applies to a large extent to the more general problem of modeling strength of preference, and will not be repeated here. We simply record the two more general aggregation models that arise as an alternative to equation (1), which emerges as a special case of either model.

Multiplicative model:

The aggregate value function $V(\mathbf{z})$ is defined by the relationship:

$$1 + kV(\mathbf{z}) = \prod_{i=1}^m [1 + kk_i v_i(z_i)] \quad (5)$$

where the $k_i > 0$ are measures of the relative importance of the associated attribute, and the parameter k is the solution to

$$1 + k = \prod_{i=1}^m [1 + kk_i] \quad (6)$$

which of necessity satisfies $k > -1$.

In the limit as $k \rightarrow 0$, we find that equation (5) tends to the additive model of equation (1) with $w_i = k_i$. In general, although the k_i can still in a sense be viewed as “importance weights”, they can no longer be arbitrarily scaled, in contrast to the weights w_i the additive multiattribute value model. Note, however, that equation (6) can be expressed as follows:

$$1 + k = 1 + k \sum_{i=1}^m k_i + k^2 \sum_{i=1}^{m-1} \sum_{j=i+1}^m k_i k_j + \cdots + k^m k_1 k_2 \dots k_m \quad (7)$$

so that if $\sum_{i=1}^m k_i = 1$, k must satisfy the equation

$$0 = k^2 \sum_{i=1}^{m-1} \sum_{j=i+1}^m k_i k_j + \cdots + k^m k_1 k_2 \dots k_m \quad (8)$$

for which the only solution is $k = 0$, giving the additive model with standardized weights.

Multilinear model:

For $k \neq 0$, the multiplicative model of equation (5) can alternatively be expressed in the following form:

$$V(\mathbf{z}) = \sum_{i=1}^m k_i v_i(z_i) + k \sum_{i=1}^{m-1} \sum_{j=i+1}^m k_i k_j v_i(z_i) v_j(z_j) + \cdots + k^{m-1} k_1 k_2 \dots k_m \times v_1(z_1) v_2(z_2) \dots v_m(z_m) \quad (9)$$

A generalization of the above, which can be shown to invoke weaker assumptions concerning preference structures, is thus the following *multilinear* aggregation:

$$V(\mathbf{z}) = \sum_{i=1}^m k_i v_i(z_i) + \sum_{i=1}^{m-1} \sum_{j=i+1}^m k_{ij} v_i(z_i) v_j(z_j) + \cdots + k_{12\dots m} v_1(z_1) v_2(z_2) \dots v_m(z_m) \quad (10)$$

Note that, whereas the multiplicative model only requires the elicitation of relative values for the k_i and the appropriate scaling (by consideration of multidimensional trade-offs), the multilinear model requires the elicitation of a much larger number of parameters, which is seldom feasible in a practical sense.

Mathematical Programming Structures

We have been assuming that the basic problem is that of choosing between a finite number of decision alternatives, which is perhaps the context within which multiattribute value modeling is most often used. There is, nevertheless, no fundamental reason for restricting application to the finite case. The construction of the MAVF is essentially independent of the decision space.

Suppose then that we have a multiobjective (vector) optimization problem of the form: maximize $z_1(\mathbf{x}), z_2(\mathbf{x}), \dots, z_m(\mathbf{x})$, subject to $\mathbf{x} \in \mathbb{X} \subset \mathbb{R}^n$. An MAVF $V(\mathbf{z})$ can still be constructed as previously described, so that the vector optimization can be replaced by the conventional scalar optimization problem: maximize $V(\mathbf{z}(\mathbf{x}))$ subject to $\mathbf{x} \in \mathbb{X}$, which can, in principle, be solved by standard constrained maximization problems.

An interesting special case is that of *multiobjective linear programming (MOLP)*, in which each of the $z_i(\mathbf{x})$ functions are linear in $\mathbf{x}$, and the feasible space $\mathbb{X}$ is defined by a set of linear constraints on the $\mathbf{x}$. linear programming (LP) is a powerful and widely used tool of management science, for which very efficient numerical algorithms exist, and it is extremely important to be able to extend these algorithms to provide efficient means of solving the MOLP problem. Multiattribute value function modeling converts the MOLP into maximization of a generally nonlinear scalar function subject to linear constraints. However, if the additive form is used, and

the partial value functions $v_i(z_i)$ are approximated by a piecewise linear form, then the problem is still soluble using standard LP solvers, although possibly requiring the introduction of binary integer variables to keep track of which segments are active.

As we have indicated earlier, the practical elicitation of partial value functions is typically carried out by consideration of a small number of discrete values for the attribute, with subsequent interpolation of the value function between these points. It can be argued that piecewise linear interpolation is no less justifiable than arbitrarily smoothed functions, and it has been shown that for purposes of decision analysis there is no practical distinction between use of a smooth curve and a piecewise linear form with as few as four segments (e.g., Stewart [5]). There is, therefore, very little loss in generality in applying piecewise linear value function modeling to exploit the power of standard LP software in solving MOLP problems.

Treatment of Risk

The previous discussion has assumed that consequences of decisions are known deterministically. Many, if not most, real-world problems include some level of risk or uncertainty of outcome. If such uncertainties can be described in probabilistic terms, then it is tempting to base decisions on the expectation of $V(a)$ for each alternative. This takes us into the realm of multiattribute utility theory, however, which is discussed in a separate article. It is demonstrated there that the expectation of an additive value function may often not be a justifiable approach, leading to consideration of the more complicated functions given by equation (5) or (10) which create practical problems of elicitation.

As an alternative to the use of expectations, it is possible to define *risk attributes*, i.e., measures of performance related to risks. Such an approach is familiar even for fundamentally single objective problems. For example, the standard Markowitz portfolio theory (cf. Jia and Dyer [8] or Goodwin and Wright [9, pp. 196–199]) represents a risky single objective (monetary reward) in terms of what are effectively two nonstochastic measures, namely, expectation and standard deviation of returns. In this sense, a single attribute decision problem under uncertainty is structured as a deterministic two-attribute decision problem. The extension to risk components for each of number of fundamental criteria

is obvious (see, for example, Millet and Wedley [10, p. 104], although this is in the context of analytic hierarchy process (AHP) rather than conventional multiattribute value theory).

The important question relates to that of identifying suitable attributes to model risk preferences in a value function model. The use of standard deviation as a measure of risk is based on special assumptions concerning either the underlying probability distribution or on the structure of risk preferences. More general measures of risk are discussed by Sarin and Weber [11] and by Jia and Dyer [8]. Other risk measures that might be included as attributes in a multiattribute value model include probabilities of occurrence of certain undesirable outcomes or quantiles of the underlying distribution.

Consider, for example, the problem of managing fisheries. An important consideration is often the risk that one or more fish populations may collapse, with serious ecological and economic consequences. A complete analysis of all possible futures resulting from a given policy may not be a practical approach. It may, nevertheless, be possible to assess probabilities that each stock falls to a critical level within the next 20 years. Such probabilities may then serve as useful attributes for MCDA, supplemented perhaps by the expectation and standard deviation of financial returns from the fishery. (See, for example, Stewart [12] for a discussion of related issues in this context.)

Time Values

Similar considerations to that of risk apply also to the problem of costs and benefits being realized at different points in time. Conventional economic analysis tends to apply geometric discount factors to future values. While there is justification for this approach when such costs or benefits are clearly financial, questions need to be raised for some of the nonfinancial measures (e.g., environmental and social impacts) that tend to arise frequently in multiattribute modeling. In such cases, there is no plausible banking system that can invest or withdraw benefits at arbitrary points in time, which is the fundamental basis for geometric discounting. Prelec and Loewenstein [13], for example, discuss a number of different functional forms for the weighting to be applied to outcomes at different points in time, derived from different

axiomatic assumptions regarding preferences over time.

A complete analysis of the appropriate discounting factors to be applied to each attribute identified is thus unlikely to be realistically a practical option, while the simplistic collapsing of future streams of costs or benefits by geometric weighting may not be justifiable for nonfinancial attributes. Much as with the risk considerations in the previous section, it is possible to define outcomes at different points in time as individual attributes in their own right, and to apply the MAVF to all of the resultant attributes.

For example, in consideration of environmental impacts from water resources planning, the base attributes may be identified as minimum flow levels during the year and pollution measured by total dissolved solids. Different policies may well generate different profiles for these measures over time. Each of the two attributes may then be subdivided into the levels of these measures after 5, 20, and 50 years, say. With little additional effort, partial value functions for levels at each point in time and relative weights can be elicited as previously described.

Multistate Models for Life Insurance Mathematics

The Scope of This Survey

Fetching its tools from a number of disciplines, actuarial science is defined by the direction of its applications rather than by the models and methods it makes use of. However, there exists at least one stream of actuarial science that presents problems and methods sufficiently distinct to merit status as an independent area of scientific inquiry – Life insurance mathematics. This is the area of applied mathematics that studies risk associated with life and pension insurance, and methods for management of such risk. Under this strict definition, its models and methods are described as they present themselves today, sustained by contemporary mathematics, statistics, and computation technology. No attempt is made to survey its two millenniums of past history, its vast collection of techniques that were needed before the advent of scientific computation, or the countless details that arise from its practical implementation to a wide range of products in a strictly regulated industry. For a brief account of statistics for multistate life history models, the reader is referred to [1].

Basic Notions of Payments and Interest

In the general context of financial services, consider a financial contract between a company and a customer. The terms and conditions of the contract generate a stream of payments, benefits from the company to the customer less contributions from the customer to the company. They are represented by a payment function

$$B(t) = \text{total amount paid in the time interval } [0, t] \quad (1)$$

$t \geq 0$, time being reckoned from the time of inception of the policy. This function is taken to be right-continuous, $B(t) = \lim_{\tau \searrow t} B(\tau)$, with existing left-limits, $B(t-) = \lim_{\tau \nearrow t} B(\tau)$. When different from 0, the jump $\Delta B(t) = B(t) - B(t-)$ represents a lump sum payment at time t . There may also be payments due continuously at rate $b(t)$ per time unit at any

time t . Thus, the payments made in any small time interval $[t, t + dt)$ total

$$dB(t) = b(t) dt + \Delta B(t) \quad (2)$$

Payments are currently invested (contributions deposited and benefits withdrawn) into an account that bears interest at rate $r(t)$ at time t . The balance of the company's account at time t , called the *retrospective reserve*, is the sum of all past and present payments accumulated with interest,

$$\mathcal{U}(t) = \int_{0-}^t e^{\int_{\tau}^t r(s) ds} d(-B)(\tau) \quad (3)$$

where $\int_{0-}^t = \int_{[0, t]}$. Upon differentiating this relationship, one obtains the dynamics

$$d\mathcal{U}(t) = \mathcal{U}(t) r(t) dt - dB(t) \quad (4)$$

showing how the balance increases with interest earned on the current reserve and net payments into the account.

The company's discounted (strictly) future net liability at time t is

$$\mathcal{V}(t) = \int_t^n e^{-\int_t^{\tau} r(s) ds} dB(\tau) \quad (5)$$

Its dynamics,

$$d\mathcal{V}(t) = \mathcal{V}(t) r(t) dt - dB(t) \quad (6)$$

shows how the debt increases with interest and decreases with net redemption.

Valuation of Financial Contracts

At any time t , the company has to provide a *prospective reserve* $V(t)$ that adequately meets its future obligations under the contract. If the future payments and interest rates are known at time t (e.g., a fixed plan savings account in an economy with fixed interest), then so would the present value in equation (5), and an adequate reserve would be $V(t) = \mathcal{V}(t)$. For the contract to be economically feasible, no party should profit at the expense of the other, so the value of the contributions must be equal to the value of the benefits at the outset:

$$\Delta B(0) + V(0) = 0 \quad (7)$$

If future payments and interest rates would be uncertain so that $\mathcal{V}(t)$ is unknown at time t , then reserving must involve some principles beyond those of mere accounting. A clear-cut case is when the

payments are *derivatives* (see **Enterprise Risk Management (ERM); Actuary; Premium Calculation and Insurance Pricing; Default Correlation**) (functions) of certain assets (securities), one of which is a money account with interest rate r . Principles for valuation of such contracts are delivered by modern financial mathematics, see [2]. We describe them briefly in lay terms. Suppose there is a finite number of basic assets that can be traded freely, in unlimited positive or negative amounts (taking long or short positions) and without transaction costs. An investment *portfolio* is given by the number of shares held in each asset at any time. The size and the composition of the portfolio may be dynamically changed through sales and purchases of shares. The portfolio is said to be *self-financing* if, after its initiation, every purchase of shares in some assets is fully financed by selling shares in some other assets (the portfolio is currently rebalanced, with no further infusion or withdrawal of capital). A self-financing portfolio is an *arbitrage* if the initial investment is negative (the investor borrows the money) and the value of the portfolio at some later time is nonnegative with probability one. A fundamental requirement for a market to be well functioning is that it does not admit arbitrage opportunities. A financial claim that depends entirely on the prices of the basic securities is called a financial *derivative*. Such a claim is said to be *attainable* if it can be perfectly reproduced by a self-financing portfolio. The no arbitrage regime dictates that the price of a financial derivative must at any time be the current value of the self-financing portfolio that reproduces it. It turns out that the price at time t of a stream of attainable derivative payments B is of the form

$$V(t) = \tilde{\mathbb{E}}[\mathcal{V}(t)|\mathcal{G}_t] \quad (8)$$

where $\tilde{\mathbb{E}}$ is the expected value under a so-called equivalent martingale measure derived from the price processes of the basic assets, and $\mathcal{G}_t$ represent all market events observed up to and including time t . Again, the contract must satisfy equation (7), which determines the initial investment $-\Delta B(0)$ needed to buy the self-financing portfolio. The financial market is *complete* (see **Equity-Linked Life Insurance; Risk Measures and Economic Capital for (Re)insurers; Weather Derivatives; Mathematical Models of Credit Risk**) if every financial derivative is attainable. If the market is

not complete, there is no unique price for every derivative, but any pricing principle obeying the no arbitrage requirement must be of the form (8).

Valuation of Life Insurance Contracts by the Principle of Equivalence

Characteristic features of life insurance contracts are, firstly, that the payments are contingent on uncertain individual life-history events (largely unrelated to market events) and, secondly, that the contracts are long term and binding to the insurer. Therefore, there exists no liquid market for such contracts and they cannot be valued by the mere principles of accounting and finance described above. Pricing of life insurance contracts and management of the risk associated with them are the paramount issues of life insurance mathematics.

The paradigm of traditional life insurance is the so-called principle of equivalence (see **Insurance Applications of Life Tables**), which is based on the notion of risk diversification in a large portfolio under the assumption that the future development of interest rates and other relevant economic and demographic conditions are known. Consider a portfolio of m contracts currently in force. Switching to calendar time, denote the payment function of contract No. i by B^i and denote its discounted future net liabilities at time t by $\mathcal{V}^i(t) = \int_t^\tau e^{-\int_t^\tau r(s)ds} dB^i(\tau)$. Let $\mathcal{H}_t$ represent the life history by time t (all individual life-history events observed up to and including time t) and introduce $\xi_i = \mathbb{E}[\mathcal{V}^i(t)|\mathcal{H}_t]$, $\sigma_i^2 = \text{Var}[\mathcal{V}^i(t)|\mathcal{H}_t]$, and $s_m^2 = \sum_{i=1}^m \sigma_i^2$. Assume that the contracts are independent and that the portfolio grows in a balanced manner such that s_m^2 goes to infinity without being dominated by any single term σ_i^2 . Then, by the central limit theorem, the standardized sum of total discounted liabilities converges in law to the standard normal distribution as the size of the portfolio increases:

$$\frac{\sum_{i=1}^m (\mathcal{V}^i(t) - \xi_i)}{s_m} \xrightarrow{L} N(0, 1) \quad (9)$$

Suppose the company provides individual reserves given by

$$V^i(t) = \xi_i + \epsilon \sigma_i^2 \quad (10)$$

for some $\epsilon > 0$. Then

$$\begin{aligned} & \mathbb{P} \left[\sum_{i=1}^m V^i(t) - \sum_{i=1}^m \mathcal{V}^i(t) > 0 \middle| \mathcal{H}_t \right] \\ &= \mathbb{P} \left[\frac{\sum_{i=1}^m (\mathcal{V}^i(t) - \xi_i)}{s_m} < \epsilon s_m \middle| \mathcal{H}_t \right] \end{aligned} \quad (11)$$

and it follows from equation (9) that the total reserve covers the discounted liabilities with a (conditional) probability that tends to 1. Similarly, taking $\epsilon < 0$ in equation (10), the total reserve covers discounted liabilities with a probability that tends to 0. The benchmark value $\epsilon = 0$ defines the *actuarial principle of equivalence*, which for an individual contract reads (dropping the topscript i):

$$V(t) = \mathbb{E} \left[\int_t^n e^{-\int_t^\tau r(s) ds} dB(\tau) \middle| \mathcal{H}_t \right] \quad (12)$$

In particular, for given benefits the premiums should be designed so as to satisfy equation (7).

Life and Pension Insurance Products

Consider a life insurance policy issued at time 0 for a finite term of n years. There is a finite set of possible states of the policy, $\mathcal{Z} = \{0, 1, \dots, J\}$, 0 being the initial state. Denote the state of the policy at time t by $Z(t)$. The uncertain course of the policy is modeled by taking Z to be a stochastic process. Regarded as a function from $[0, n]$ to $\mathcal{Z}$, Z is assumed to be right-continuous, with a finite number of jumps, and commencing from $Z(0) = 0$. We associate with the process Z the *indicator processes* I_g and *counting processes* N_{gh} defined, respectively, by $I_g(t) = 1[Z(t) = g]$ (1 or 0 according as the policy is in the state g or not at time t) and $N_{gh}(t) = \sharp\{\tau; Z(\tau-) = g, Z(\tau) = h, \tau \in (0, t]\}$ (the number of transitions from state g to state h ($\neq g$) during the time interval $(0, t]$).

The payments B generated by an insurance policy are typically of the form

$$dB(t) = \sum_g I_g(t) dB_g(t) + \sum_{g \neq h} b_{gh}(t) dN_{gh}(t) \quad (13)$$

where each B_g is a payment function specifying payments due during sojourns in state g (a general *life annuity*) (see **Asset–Liability Management for Life Insurers; Equity-Linked Life Insurance; Insurance Applications of Life Tables; Longevity Risk and Life Annuities**), and each b_{gh} specifying lump sum payments due upon transitions from state g to state h (a general *life assurance*). When different from 0, $\Delta B_g(t)$ represents a lump sum (general *life endowment*) payable in state g at time t . Positive amounts represent benefits and negative amounts represent premiums. In practice premiums are only of annuity type.

Figure 1 shows a flow-chart for a policy on a single life with payments dependent only on survival and death. We list the basic forms of benefits: an n -year *term insurance* (see **Options and Guarantees in Life Insurance; Risk Classification/Life**) with sum insured 1 payable immediately upon death, $b_{01}(t) = 1[t \in (0, n)]$; an n -year *life endowment* with sum 1, $\Delta B_0(n) = 1$; An n -year *life annuity* payable annually in arrears, $\Delta B_0(t) = 1, t = 1, \dots, n$; An n -year *life annuity* payable continuously at rate 1 per year, $b_0(t) = 1[t \in (0, n)]$; An $(n - m)$ -year *annuity* deferred in m years payable continuously at rate 1 per year, $b_0(t) = 1[t \in (m, n)]$. Thus, an n -year *term insurance* with sum insured b against premium payable continuously at rate c per year is given by $dB(t) = b dN_{01}(t) - c I_0(t) dt$ for $0 \leq t < n$ and $dB(t) = 0$ for $t \geq n$.

The flow-chart in Figure 2 is apt to describe a single-life policy with payments that may depend on the state of health of the insured. For instance, an n -year *endowment insurance* (a combined term insurance and life endowment) with sum insured b , against premium payable continuously at rate c while active (waiver of premium during disability), is given by $dB(t) = b (dN_{02}(t) + dN_{12}(t)) - c I_0(t) dt$,

Figure 1 A single-life policy with two states

Figure 2 A single-life policy with three states

$0 \leq t < n$, $\Delta B(n) = b(I_0(n) + I_1(n))$, $dB(t) = 0$ for $t > n$.

The flow-chart in Figure 3 is apt to describe a multilife policy involving three lives called x , y , and z . For instance, an n -year insurance with sum b payable upon the death of the last survivor against premium payable as long as all three are alive is given by $dB(t) = b(dN_{47}(t) + dN_{57}(t) + dN_{67}(t)) - cI_0(t) dt$, $0 \leq t < n$, $dB(t) = 0$ for $t \geq n$.

The Markov Chain Model for the Policy History

The breakthrough of stochastic processes in life insurance mathematics was marked by Hoem's 1969 paper [3], where the process Z was modeled as a

time-continuous Markov chain. The Markov property means that the future course of the process is independent of its past if the present state is known: For $0 < t_1 < \dots < t_q$ and $j_1, \dots, j_q$ in $\mathcal{Z}$,

$$\begin{aligned} \mathbb{P}[Z(t_q) = j_q \mid Z(t_p) = j_p, \quad p = 1, \dots, q-1] \\ = \mathbb{P}[Z(t_q) = j_q \mid Z(t_{q-1}) = j_{q-1}] \end{aligned} \quad (14)$$

It follows that the *simple transition probabilities*,

$$p_{gh}(t, u) = \mathbb{P}[Z(u) = h \mid Z(t) = g] \quad (15)$$

determine the finite-dimensional marginal distributions through

$$\begin{aligned} \mathbb{P}[Z(t_p) = j_p, \quad p = 1, \dots, q] \\ = p_{0j_1}(0, t_1)p_{j_1j_2}(t_1, t_2) \cdots p_{j_{q-1}j_q}(t_{q-1}, t_q) \end{aligned} \quad (16)$$

hence they also determine the entire probability law of the process Z . It is moreover assumed that, for each pair of states $g \neq h$ and each time t , the limit

$$\mu_{gh}(t) = \lim_{u \searrow t} \frac{p_{gh}(t, u)}{u - t} \quad (17)$$

Figure 3 A policy involving three lives x , y , z . An expired life is replaced by a dagger $\dagger$

exists. It is called the *intensity of transition* from state g to state h at time t . In other words,

$$p_{gh}(t, u) = \mu_{gh}(t) dt + o(dt) \quad (18)$$

where $o(dt)$ denotes a term such that $o(dt)/dt \rightarrow 0$ as $dt \rightarrow 0$. The intensities, being one dimensional and easy to interpret as “instantaneous conditional probabilities of transition per time unit”, are the basic entities in the probability model. They determine the simple transition probabilities uniquely as solutions to sets of differential equations. The *Kolmogorov backward differential equations* for the $p_{jg}(t, u)$, seen as functions of $t \in [0, u]$ for fixed g and u , are

$$\frac{\partial}{\partial t} p_{jg}(t, u) = - \sum_{k: k \neq j} \mu_{jk}(t) (p_{kg}(t, u) - p_{jg}(t, u)) \quad (19)$$

with side conditions $p_{gg}(u, u) = 1$ and $p_{jg}(u, u) = 0$ for $j \neq g$. The *Kolmogorov forward equations* for the $p_{gj}(s, t)$, seen as functions of $t \in [s, n]$ for fixed g and s , are

$$\frac{\partial}{\partial t} p_{gj}(s, t) = \sum_{i: i \neq j} p_{gi}(s, t) \mu_{ij}(t) - p_{gj}(s, t) \mu_{j \cdot}(t) \quad (20)$$

with obvious side conditions at $t = s$. The forward equations are sometimes the more convenient because, for any fixed g, s, t , the functions $p_{gj}(s, t)$, $j = 0, \dots, J$, are probabilities of disjoint events and therefore sum to 1. A technique for obtaining such differential equations is sketched in the section titled “Actuarial Analysis of Standard Insurance Products”.

A differential equation for the *sojourn probability*,

$$p_{\overline{gg}}(t, u) = \mathbb{P}[Z(\tau) = g, \tau \in (t, u) | Z(t) = g] \quad (21)$$

is easily put up and solved to give

$$p_{\overline{gg}}(t, u) = e^{-\int_t^u \mu_{g \cdot}(s) ds} \quad (22)$$

where $\mu_{g \cdot}(t) = \sum_{h, h \neq g} \mu_{gh}(t)$ is the *total intensity of transition* out of state g at time t . To see that the intensities govern the probability law of the process Z , consider a fully specified path of Z , starting from the initial state $g_0 = 0$ at time $t_0 = 0$, sojourning there

until time t_1 , making a transition from g_0 to g_1 in $[t_1, t_1 + dt_1)$, sojourning there until time t_2 , making a transition from g_1 to g_2 in $[t_2, t_2 + dt_2)$, and so on until making its final transition from g_{q-2} to g_{q-1} in $[t_{q-1}, t_{q-1} + dt_{q-1})$, and sojourning there until time $t_q = n$. The probability of this elementary event is a product of sojourn probabilities and infinitesimal transition probabilities, hence a function only of the intensities:

$$\begin{aligned} & e^{-\int_{t_0}^{t_1} \mu_{g_0 \cdot}(s) ds} \mu_{g_0 g_1}(t_1) dt_1 e^{-\int_{t_1}^{t_2} \mu_{g_1 \cdot}(s) ds} \\ & \times \mu_{g_1 g_2}(t_2) dt_2 \dots e^{-\int_{t_{q-1}}^{t_q} \mu_{g_{q-1} \cdot}(s) ds} \\ & = e^{\sum_{p=1}^{q-1} \ln \mu_{g_{p-1} g_p}(t_p) - \sum_{p=1}^q \sum_{h: h \neq g_{p-1}} \int_{t_{p-1}}^{t_p} \mu_{g_{p-1} h}(s) ds} \\ & \times dt_1 \dots dt_{q-1} \end{aligned} \quad (23)$$

Actuarial Analysis of Standard Insurance Products

The bulk of existing life insurance mathematics deals with the situation where the functions B_g and b_{gh} depend only on the life history of the individual(s) covered under the policy. We refer to such products as *standard*. Moreover, interest rates and intensities of transition are assumed to be deterministic (known at time zero).

We consider, first, simple products with payments $dB_g(t)$ and $b_{gh}(t)$ depending only on the policy duration t (as the notation indicates). Then, with “memoryless” payments and policy process (the Markov assumption), the reserve in equation (12) is a function of the time t and the current policy state $Z(t)$ only. Therefore, we need only determine the state-wise reserves

$$V_j(t) = \mathbb{E} \left[\int_t^n e^{-\int_t^\tau r(s) ds} dB(\tau) \middle| Z(t) = j \right] \quad (24)$$

Inserting equation (13) into equation (24) and using the obvious relationships

$$\mathbb{E} [I_g(\tau) | Z(t) = j] = p_{jg}(t, \tau) \quad (25)$$

$$\mathbb{E} [dN_{gh}(\tau) | Z(t) = j] = p_{jg}(t, \tau) \mu_{gh}(\tau) d\tau \quad (26)$$

we obtain

$$V_j(t) = \int_t^n e^{-\int_t^\tau r(s) ds} \sum_g p_{jg}(t, \tau) \times \left(dB_g(\tau) + \sum_{h; h \neq g} \mu_{gh}(\tau) b_{gh}(\tau) d\tau \right) \quad (27)$$

It is an almost universal principle in continuous-time stochastic processes theory that conditional expected values of functions of the future, given the past, are solutions to certain differential equations. More often than not, these are needed in order to construct the solution. Therefore, the theory of differential equations and numerical methods for solving them are part and parcel of stochastic processes and their applications.

The state-wise reserves V_j satisfy the first-order ordinary differential equations (ODE)

$$\begin{aligned} \frac{d}{dt} V_j(t) &= r(t) V_j(t) - b_j(t) \\ &\quad - \sum_{k; k \neq j} \mu_{jk}(t) (b_{jk}(t) + V_k(t) - V_j(t)) \end{aligned} \quad (28)$$

valid at all times t where the coefficients r , μ_{jk} , b_j , and b_{jk} are continuous, and there are no lump sum annuity payments. The ultimo conditions

$$V_j(n-) = \Delta B_j(n) \quad (29)$$

$j = 1, \dots, J$, follow from the very definition of the reserve. Likewise, at times t where annuity lump sums are due,

$$V_j(t-) = \Delta B_j(t) + V_j(t) \quad (30)$$

The equation (28) are so-called backward differential equations since the solution is to be computed backwards starting from equation (29).

The differential equations can be derived in various ways. We will sketch a simple heuristic method called *direct backward construction*, which works due to the piecewise deterministic behavior of the Markov chain. Split the expression on the right of equation (5) into

$$\mathcal{V}(t) = dB(t) + e^{-r(t)dt} \mathcal{V}(t+dt) \quad (31)$$

(suppressing a negligible term $o(dt)$) and condition on what happens in the time interval $(t, t+dt]$. With probability $1 - \mu_{j\cdot}(t) dt$ the policy stays in state j and, conditional on this, $dB(t) = b_j(t) dt$ and the expected value of $\mathcal{V}(t+dt)$ is $V_j(t+dt)$. With probability $\mu_{jk}(t) dt$ the policy moves to state j and, conditional on this, $dB(t) = b_{jk}(t)$ and the expected value of value of $\mathcal{V}(t+dt)$ is $V_k(t+dt)$. One gathers

$$\begin{aligned} V_j(t) &= (1 - \mu_{j\cdot}(t) dt) (b_j(t)dt + e^{-r(t)dt} V_j(t+dt)) \\ &\quad + \sum_{k; k \neq j} \mu_{jk}(t) dt (b_{jk}(t) + e^{-r(t)dt} V_k(t+dt)) \\ &\quad + o(dt) \end{aligned} \quad (32)$$

Rearranging, dividing by dt , and letting $dt \rightarrow 0$, one arrives at equation (28). In the single-life model sketched in Figure 1, consider an endowment insurance with sum b against premium at level rate c under constant interest rate r . The differential equation for V_0 is

$$\frac{d}{dt} V_0(t) = r V_0(t) + c - \mu(t) (b - V_0(t)) \quad (33)$$

subject to $V_0(n-) = b$. This is *Thiele's differential equation*, discovered in 1875.

The expression on the right of equation (28) shows how the reserve, seen as a debt, increases with interest (first term) and decreases with redemption of annuity type in the current state (second term), and of lump sum type upon transition to other states (third term). The quantity

$$R_{jk} = b_{jk}(t) + V_k(t) - V_j(t) \quad (34)$$

appearing in the third term is called the *sum at risk* in respect of transition from state j to state k at time t since it is the amount credited to the insured's account upon such a transition: the lump sum payable immediately plus the adjustment of the reserve. This sum multiplied with the rate $\mu_{jk}(t)$ is a rate of expected payments. Solving equation (28) with respect to $-b_j(t)$, which can be seen as a premium (rate), shows that the premium consists of a *savings premium* $\frac{d}{dt} V_j(t) - r(t) V_j(t)$ needed to maintain the reserve (the increase of the reserve less the interest it earns), and a *risk premium* $\sum_{k; k \neq j} \mu_{jk}(t) R_{jk}(t)$ needed to cover risk due to transitions.

The differential equations (28) are as transparent as the defining integral expression (27) themselves, but there are other and more important reasons why they are useful.

Firstly, the easiest (and sometimes the only) way of computing the values of the reserves is by solving the differential equations numerically (e.g., by some finite difference method). The coefficients in the equations are precisely the elemental functions that are specified in the model and in the contract. Thus all values of the state-wise reserves are obtained in one run. The integrals (equation 27) might be computed numerically, but that would require separate computation of the transition probabilities as functions of τ for each given t . In general, the transition probabilities are themselves compound quantities that can only be obtained as solutions to differential equations.

Secondly, the differential equations are indispensable constructive tools when more complicated products are considered. For instance, if the life endowment contract behind equation (33) is modified such that 50% of the reserve is paid out upon death in addition to the sum insured, then its differential equation becomes

$$\frac{d}{dt} V_0(t) = r V_0(t) + c - \mu(t) (b - 0.5 V_0(t)) \quad (35)$$

which is just as easy as equation (33). Another case in point is administrative expenses, which are treated as benefits and covered by charging the policyholder an extra premium in accordance with the equivalence principle. Such expenses may incur upon the inception of the policy (included in $\Delta B_0(0)$), as annuity type payments (included in the $b_g(t)$), and in connection with payments of death and endowment benefits (included in the $b_{gh}(t)$ and the $\Delta B_g(t)$). In particular, expenses related to the company's investment operations are typically allocated to the individual policies on a pro rata basis, in proportion to their individual reserves. Thus, for our generic policy, there is a cost element running at rate $\gamma(t) V_j(t)$ at time t in state j . Subtracting this term on the right-hand side of equation (28) creates no difficulty and, virtually, is just to the effect of reducing the interest rate $r(t)$.

The noncentral conditional moments

$$V_j^{(q)}(t) = \mathbb{E}[\mathcal{V}(t)^q | Z(t) = j] \quad (36)$$

$q = 1, 2, \dots$, do not in general possess explicit integral expressions. They are, however, solutions to

the backward differential equations

$$\begin{aligned} \frac{d}{dt} V_j^{(q)}(t) &= (qr(t) + \mu_j(t)) V_j^{(q)}(t) \\ &\quad - q b_j(t) V_j^{(q-1)}(t) - \sum_{k; k \neq j} \mu_{jk}(t) \\ &\quad \times \sum_{p=0}^q \binom{q}{p} (b_{jk}(t))^p V_k^{(q-p)}(t) \end{aligned} \quad (37)$$

subject to the conditions $V_j^{(q)}(n-) = \Delta B_j(n)^q$ (plus joining conditions at times with annuity lump sums). The backward argument goes as for the reserves, only with a few more details to attend to, starting from

$$\begin{aligned} \mathcal{V}(t)^q &= (dB(t) + e^{-r(t)dt} \mathcal{V}(t+dt))^{q-p} \\ &= \sum_{p=0}^q \binom{q}{p} dB(t)^p e^{-r(t)dt(q-p)} \mathcal{V}(t+dt)^{q-p} \end{aligned} \quad (38)$$

Higher-order moments shed light on the risk associated with the portfolio. Recalling equation (9) and using the notation in the section titled “Valuation of Life Insurance Contracts by the Principle of Equivalence”, a solvency margin approximately equal to the upper ε -fractile in the distribution of the discounted outstanding net liability is given by $\sum_{i=1}^m \xi_i + c_{1-\varepsilon} s_m$, where $c_{1-\varepsilon}$ is the upper ε -fractile of the standard normal distribution. More refined estimates of the fractiles of the total liability can be obtained by involving three or more moments.

Path-Dependent Payments and Semi-Markov Models

The technical matters in the sections “The Markov Chain Model for the Policy History” and “Actuarial Analysis of Standard Insurance Products” become more involved if the contractual payments or the transition intensities depend on the past life history. We will consider examples where they may depend on the sojourn time $S(t)$ that has elapsed since entry into the current state, henceforth called the *state duration*. Thus, if $Z(t) = j$ and $S(t) = s$ at policy

duration t , the transition intensities and payments are of the form $\mu_{jk}(s, t)$, $b_j(s, t)$, and $b_{jk}(s, t)$. To ease exposition, we disregard intermediate lump sum annuities, but allow for terminal endowments $\Delta B_j(s, n)$ at time n . The state-wise reserve will now be a function of the form $V_j(s, t)$.

In simple situations (e.g., no possibility of return to previously visited states), one may still work out integral expressions for probabilities and reserves (they will be multiple integrals). The differential equation approach always works, however. The relationship (32) modifies to

$$\begin{aligned} V_j(s, t) = & (1 - \mu_{jj}(s, t) dt) \\ & \times (b_j(s, t) dt + e^{-r(t)dt} V_j(s + dt, t + dt)) \\ & + \sum_{k: k \neq j} \mu_{jk}(s, t) dt (b_{jk}(s, t) + V_k(0, t)) \\ & + o(dt) \end{aligned} \quad (39)$$

from which one obtains the first-order partial differential equations

$$\begin{aligned} \frac{\partial}{\partial t} V_j(s, t) = & r(t) V_j(s, t) - \frac{\partial}{\partial s} V_j(s, t) - b_j(s, t) \\ & - \sum_{k: k \neq j} \mu_{jk}(s, t) \\ & \times (b_{jk}(s, t) + V_k(0, t) - V_j(s, t)) \end{aligned} \quad (40)$$

subject to the conditions

$$V_j(s, n-) = \Delta B_j(s, n) \quad (41)$$

We give two examples of payments dependent on state duration. In the framework of the disability model in Figure 2, an n -year disability annuity payable at rate 1 only after a qualifying period of q , is given by $b_1(s, t) = 1[q < s < t < n]$. In the framework of the three-lives model sketched in Figure 3, an n -year term insurance of 1 payable upon the death of y if z is still alive and x is dead and has been so for at least q years, is given by $b_{14}(s, t) = 1[q < s < t < n]$.

Probability models with intensities dependent on state duration are known as a *semi-Markov models*. A case in support of their relevance is the disability model in Figure 2. If there are various forms of disability, then the state duration may carry information

about the severity of the disability and hence about prospects of longevity and recovery.

Managing Nondiversifiable Risk for Standard Insurance Products

Life insurance policies are typically long-term contracts, with time horizons wide enough to see substantial variations in interest, mortality, and other economic and demographic conditions affecting the economic result of the portfolio. The rigid conditions of the standard contract leave no room for the insurer to meet adverse developments of such conditions; he cannot cancel contracts that are in force, nor can he reduce their benefits or raise their premiums. Therefore, with standard insurance products there is associated a risk that cannot be diversified by increasing the size of the portfolio as in the section “Valuation of Life Insurance Contracts by the Principle of Equivalence”. The limit operation leading to equation (12) was made under the assumption of fixed interest. In an extended setup, with random economic and demographic factors, this amounts to conditioning on $\mathcal{G}_n$, the economic and demographic development over the term of the contract. Instead of equation (12), one gets

$$V(t) = \mathbb{E} \left[\int_t^n e^{-\int_t^\tau r(s) ds} dB(\tau) \middle| \mathcal{H}_t, \mathcal{G}_n \right] \quad (42)$$

At time t only $\mathcal{H}_t$ and $\mathcal{G}_t$ are known, so equation (42) is not a feasible reserve. In particular, the equivalence principle equation (7), recast as

$$\Delta B_0(0) + \mathbb{E} \left[\int_0^n e^{-\int_0^\tau r(s) ds} dB(\tau) \middle| \mathcal{G}_n \right] = 0 \quad (43)$$

is also infeasible since benefits and premiums are fixed at time 0 when $\mathcal{G}_n$ cannot be anticipated. The traditional way of managing the nondiversifiable risk is to charge premiums sufficiently high to cover, on the average in the portfolio, the contractual benefits under all likely economic-demographic scenarios. The systematic surpluses that (most likely) will be generated by such prudently calculated premiums belong to the insured and are paid back in arrears as the history $\mathcal{G}_t$ unfolds. Such contracts are called *participating policies* or *with-profit contracts*.

The repayments, called *dividends* or *bonus*, are represented by a payment function D . They should be controlled in such a manner as to ultimately restore equivalence when the full history is known at time n :

$$\Delta B_0(0) + \mathbb{E} \left[\int_0^n e^{-\int_0^\tau r(s) ds} (dB(\tau) + dD(\tau)) \middle| \mathcal{G}_n \right] = 0 \quad (44)$$

A common way of designing the prudent premium plan is, in the framework of the preceding five sections, to calculate premiums and reserves on a so-called technical basis with interest rate r^* and transition intensities μ_{jk}^* that represent a worst-case-scenario. Equipping all technical quantities with an asterisk, we denote the corresponding reserves by V_j^* , the sums at risk by R_{jk}^* etc. The surplus generated by time t is, quite naturally, defined as the excess of the factual retrospective reserve over the contractual prospective reserve,

$$S(t) = \mathcal{U}(t) - \sum_{j=0}^J I_j V_j^*(t) \quad (45)$$

Upon differentiating this expression, using equations (4), (13), and (28), and the obvious relationship $dI_j(t) = \sum_{k; k \neq j} (dN_{kj}(t) - dN_{jk}(t))$, one obtains after some rearrangement that

$$dS(t) = S(t) r(t) dt + dC(t) + dM(t) \quad (46)$$

where

$$dC(t) = \sum_{j=0}^J I_j(t) c_j(t) dt \quad (47)$$

$$c_j(t) = (r(t) - r^*) V_j^*(t) + \sum_{k; k \neq j} R_{jk}^*(t) (\mu_{jk}^*(t) - \mu_{jk}(t)) \quad (48)$$

$$dM(t) = - \sum_{j \neq k} R_{jk}^*(t) (dN_{jk}(t) - I_j(t) \mu_{jk}(t) dt) \quad (49)$$

The right-hand side of equation (46) displays the dynamics of the surplus. The first term is the interest earned on the current surplus. The last term, given

by equation (49), is purely erratic and represents the policy's instantaneous random deviation from the expected development. The second term, given by equation (47), is the systematic contribution to surplus, and equation (48) shows how it decomposes into gains due to prudent assumptions about interest and transition intensities in each state. One may show that equation (44) is equivalent to

$$\mathbb{E} \left[\int_0^n e^{-\int_0^\tau r(s) ds} (dC(\tau) - dD(\tau)) \middle| \mathcal{G}_n \right] = 0 \quad (50)$$

which says that, on the average over the portfolio, all surpluses are to be repaid as dividends.

The dividend payments D are controlled by the insurer. Since negative dividends are not allowed, it is possible that equation (50) cannot be ultimately attained if the contributions to surplus turn negative (the technical basis was not sufficiently prudent) and/or dividends were paid out prematurely. Designing the dividend plan D is therefore a major issue, and it can be seen as a problem in optimal stochastic control theory. For a general account of the point process version of this theory, see [4]. Various schemes used in practice are described in [5]. The simplest (and least cautious one) is the so-called contribution plan, whereby surpluses are repaid currently as they arise: $D = C$.

The much discussed issue of *guaranteed interest* takes a clear form in the framework of the present theory. Focusing on interest, suppose the technical intensities μ_{jk}^* are the same as the factual μ_{jk} so that the surplus emerges only from the excess of the factual interest rate $r(t)$ over the technical rate r^* :

$$dC(t) = (r(t) - r^*) V_{Z(t)}^*(t) dt \quad (51)$$

Under the contribution plan, $dD(t)$ must be set to 0 if $dC(t) < 0$, and the insurer will therefore have to cover the negative contributions $dC^-(t) = (r^* - r(t))_+ V_{Z(t)}^*(t) dt$. Averaging out the life-history randomness, the discounted value of these claims is

$$\int_0^n e^{-\int_0^\tau r(s) ds} (r^* - r(\tau))_+ \sum_{j=0}^J p_{0j}(0, \tau) V_j^*(\tau) d\tau \quad (52)$$

Mobilizing the principles of arbitrage pricing theory set out in the section titled "Valuation of

Financial Contracts,” we conclude that the interest guarantee inherent in the present scheme has a market price which is the expected value of equation (52) under the equivalent martingale measure. Charging a down premium equal to this price at time 0 would eliminate the downside risk of the contribution plan without violating the format of the with-profit scheme.

Unit-Linked Insurance

The dividends D redistributed to holders of standard with-profit contracts can be seen as a way of adapting the benefits payments to the development of the nondiversifiable risk factors of $\mathcal{G}_t$, $0 < t \leq n$. Alternatively, one could specify in the very terms of the contract, that the payments will depend, not only on life-history events, but also on the development of interest, mortality, and other economic-demographic conditions. One such approach is the unit-linked contract, which relates the benefits to the performance of the insurer’s investment portfolio. To keep things simple, let the interest rate $r(t)$ be the only uncertain nondiversifiable factor. A straightforward way of eliminating the interest rate risk is to let the payment function under the contract be of the form

$$dB(t) = e^{\int_0^t r(s) ds} dB^\circ(t) \quad (53)$$

where B° is a baseline payment function dependent only on the life history. This means that all payments, premiums and benefits, are index-regulated with the value of a unit of the investment portfolio. Inserting this into equation (43), assuming that life-history events and market events are independent, the equivalence requirement becomes

$$\Delta B_0^\circ(0) + \mathbb{E} \left[\int_0^n dB^\circ(\tau) \right] = 0 \quad (54)$$

This requirement does not involve the future interest rates and can be met by setting an equivalence baseline premium level at time 0.

Perfect unit-linked products of the form (53) are not offered in practice. Typically, only the sum insured (e.g., a term insurance or a life endowment) is index-regulated, while the premiums are not. Moreover, the contract usually comes with a guarantee that the sum insured will not be less

than a certain nominal amount. Averaging out over the life histories, the payments become purely financial derivatives, and pricing goes by the principles described in the section “Valuation of Financial Contracts”. If random life-history events are kept part of the model, one faces a pricing problem in an incomplete market. This problem was formulated and solved in [6] in the framework of the theory of risk minimization [7].

Defined Benefits and Defined Contributions

With-profit and unit-linked insurance schemes are just two ways of adapting benefits to the long-term development of nondiversifiable risk factors. The former does not include the adaptation rule in the terms of the contract, whereas the latter does. We mention two other arch-type insurance schemes that are widely used in practice. *Defined benefits* means literally that the benefits are specified in the contract, either in nominal figures as in the with-profit contract or in units of some index. A commonly used index is the salary (final or average) of the insured. In that case also, the contributions (premiums) are usually linked to the salary (typically a certain percentage of the annual income). Risk management of such a scheme is a matter of designing the rule for collection of contributions. Unless the future benefits can be precisely predicted or reproduced by dynamic investment portfolios, defined benefits leave the insurer with a major nondiversifiable risk. Defined benefits are gradually being replaced with their opposite, *defined contributions*, with only premiums specified in the contract. This scheme has much in common with the traditional with-profit scheme, but leaves more flexibility to the insurer as benefits do not come with a minimum guarantee.

Securitization

Generally speaking, and recalling the section “Valuation of Financial Contracts,” any introduction of new securities in a market helps to complete it (see **Securitization/Life**). *Securitization* means creating tradeable securities that may serve to make nontraded claims attainable. This device, well known and widely used in the commodities

markets, was introduced in nonlife insurance in the 1990s when exchanges and insurance corporations launched various forms of *insurance derivatives* aimed to transfer catastrophe risk to the financial markets. Securitization of nondiversifiable risk in life insurance, e.g., through bonds with coupons related to mortality experience, is conceivable. If successful, it would open new opportunities of financial management of life insurance risk by the principles described in the section “Valuation of Financial Contracts”. A work in this spirit is [8], where market attitudes are modeled for all forms of risk associated with a life insurance portfolio, leading to market values for reserves.

A View to the Literature

In this brief survey of contemporary life insurance mathematics, space has not been devoted to the wealth of techniques that are now mainly only of historical interest, and no attempt has been made to trace the origins of modern ideas and results. References to the literature are selected accordingly, their purpose being to add details to the broad picture drawn here. A key reference on the early history of life insurance mathematics is [11]. Textbooks covering classical insurance mathematics are [12–16]. An account of counting processes and martingale techniques in life insurance mathematics can be compiled from [5, 17].

RAGNAR NORBERG

Multistate Systems

All technical systems are designed to perform their intended tasks in a given environment. Some systems can perform their tasks with various distinguished levels of intensity usually referred to as *performance rates*. A system that can have a finite number of performance rates is called a *multistate system* (MSS) (see **Reliability Optimization**). Usually MSS is composed of elements that in turn can be multistate ones. An element is an entity in a system, which is not further subdivided. This does not imply that an element cannot be made of parts, but means only that, in a given reliability study, it is regarded as a self-contained unit and is not analyzed in terms of the reliability performances of its constituents.

Actually, a binary system is the simplest case of an MSS having two distinguished states (perfect functioning and complete failure).

There are different situations where a system is considered to be an MSS:

1. Any system consisting of different units that have a cumulative effect on the performance of the entire system has to be considered as an MSS. Indeed, the performance rate of such a system depends on the availability of its units, as the different numbers of the available units can provide different levels of the task performance.

The simplest example of such a situation is the well-known k -out-of- n systems. These systems consist of n identical binary units and can have $n + 1$ states depending on the number of available units. The system performance rate is assumed to be proportional to the number of available units. It is assumed that the performance rates corresponding to more than $k - 1$ available units are acceptable. When the contributions of different units to the performance rate of the cumulative system are different, the number of possible MSS states grows dramatically as different combinations of k available units can provide different performance rates for the entire system.

2. The performance rate of elements composing a system can also vary as a result of their deterioration (fatigue, partial failures) or because of variable ambient conditions. Element failures

can lead to the degradation of the entire MSS performance.

The performance rates of the elements can range from perfect functioning up to complete failure. The failures that lead to the decrease in the element performance are called *partial failures*. After partial failure, elements continue to operate at reduced performance rates, and after complete failure, the elements are totally unable to perform their tasks.

Consider the following two examples of MSSs:

- In the power supply system consisting of generating and transmitting facilities, each generating unit can function at different levels of capacity. Generating units are complex assemblies of many parts. The failures of different parts may lead to situations where the generating unit continues to operate, but at a reduced capacity. This can occur during the outages of several auxiliaries such as pulverizers, water pumps, fans, etc.
- In a wireless communication system consisting of transmission stations, the state of each station is defined by the number of subsequent stations covered in its range. This number depends not only on the availability of station amplifiers, but also on the conditions for signal propagation that depend on weather, solar activity, etc.

Generic Model of Multistate System

To analyze MSS behavior, one has to know the characteristics of its elements. Any system element j can have $k_j + 1$ different states corresponding to the performance rates, represented by the set $\mathbf{g}_j = \{g_{j0}, g_{j1}, \dots, g_{jk_j}\}$, where g_{jh} is the performance rate of element j in the state h , $h \in \{0, 1, \dots, k_j\}$. The performance rate G_j of element j at any time instant is a random variable that takes its values from $\mathbf{g}_j : G_j \in \mathbf{g}_j$. The probabilities associated with the different states (performance rates) of the system element j can be represented by the set

$$p_j = \{p_{j0}, p_{j1}, \dots, p_{jk_j}\} \quad (1)$$

where

$$p_{jh} = \Pr\{G_j = g_{jh}\} \quad (2)$$

Since the element's states compose the complete group of mutually exclusive events (meaning that the element can always be in one and only in one of $k_j + 1$ states)

$$\sum_{h=0}^{k_j} p_{jh} = 1 \quad (3)$$

Expression (2) defines the probability mass function (pmf) of a discrete random variable G_j . The collection of pairs $g_{jh}, p_{jh}, h = 0, 1, \dots, k_j$, completely determines the performance distribution of element j .

When the MSS consists of n independent elements, its performance rate is unambiguously determined by the performance rates of these elements. At each moment, the system elements have certain performance rates corresponding to their states. The state of the entire system is determined by the states of its elements. Assume that the entire system has $K + 1$ different states and that v_i is the entire system's performance rate in state $i \in \{0, \dots, K\}$. The MSS performance rate is a random variable V that takes values from the set $M = \{v_1, \dots, v_K\}$.

Let

$$L^n = \{g_{10}, \dots, g_{1k_1}\} \times \{g_{20}, \dots, g_{2k_2}\} \times \dots \times \{g_{n0}, \dots, g_{nk_n}\} \quad (4)$$

be the space of possible combinations of performance rates for all of the system elements and $M = \{v_0, \dots, v_K\}$ be the space of possible values of the performance rate for the entire system. The transform $\phi(G_1, \dots, G_n) : L^n \rightarrow M$, which maps the space of the elements' performance rates into the space of system's performance rates, is named the *system structure function* (see **Imprecise Reliability**).

The generic model of the MSS includes the pmf of performances for all the system elements and system structure function [1]:

$$g_j, p_j, \quad 1 \leq j \leq n \quad (5)$$

$$V = \phi(G_1, \dots, G_n) \quad (6)$$

From this model, one can obtain the pmf of the entire system's performance in the form

$$q_i, v_i, 0 \leq i \leq K, \text{ where } q_i = \Pr\{V = v_i\} \quad (7)$$

Measures of Risk

The acceptability of system state can be usually defined by the acceptability function $f(V, \theta)$ representing the desired relation between the system performance V and some limit value θ named *system demand* ($f(V, \theta) = 1$ if the system performance is acceptable and $f(V, \theta) = 0$ otherwise). The MSS reliability is defined as its expected acceptability (probability that the MSS satisfies the demand) [2]. Having the system pmf (equation (7)) one can obtain its reliability as expected value of the acceptability function $E[f(V, \theta)]$:

$$R(\theta) = E[f(V, \theta)] = \sum_{i=1}^K q_i f(v_i, \theta) \quad (8)$$

For example, in applications where the system performance is defined as a task execution time and θ is the maximum allowed task execution time, equation (8) takes the form

$$R(\theta) = \sum_{i=1}^K q_i 1(v_i < \theta) \quad (9)$$

and in applications where the system performance is defined as system productivity (capacity) and θ is the minimum allowed productivity, equation (8) takes the form

$$R(\theta) = \sum_{i=1}^K q_i 1(v_i > \theta) \quad (10)$$

where $1(\cdot)$ is unity function: $1(\text{TRUE}) = 1$, $1(\text{FALSE}) = 0$.

The risk measure named unreliability is defined as $1 - R(\theta)$.

Another important measure of the risk associated with system performance reduction is the expected unsupplied demand $W(\theta)$. It can be obtained as

$$W(\theta) = \sum_{i=1}^K q_i \cdot |v_i - \theta| \cdot (1 - f(v_i, \theta)) \quad (11)$$

To calculate the indices $R(\theta)$ and $W(\theta)$, one has to obtain the pmf of the MSS random performance in the equation (7) from the model (5) and (6). The reliability block diagram (RBD) (see **Systems Reliability; Markov Modeling in Reliability**) method for obtaining the performance distribution

for series–parallel MSS is based on the universal generating function (u -function) technique, which was introduced in [3] and proved to be very effective for the reliability evaluation of different types of MSSs [2].

Evaluating the Risk Associated with MSS Performance Reduction

Universal Generating Function (u -Function) Technique

The u -function representing the pmf of a discrete random variable Y_j is defined as a polynomial

$$u_j(z) = \sum_{h=0}^{k_j} \alpha_{jh} z^{y_{jh}} \quad (12)$$

where the variable Y_j has $k_j + 1$ possible values and $\alpha_{jh} = \Pr\{Y_j = y_{jh}\}$.

To obtain the u -function representing the pmf of a function of n independent random variables $\varphi(Y_1, \dots, Y_n)$, the following composition operator is used:

$$\begin{aligned} U(z) &= \otimes_{\varphi}(u_1(z), \dots, u_n(z)) \\ &= \otimes_{\varphi} \left(\sum_{h_1=0}^{k_1} \alpha_{1h_1} z^{y_{1h_1}}, \dots, \sum_{h_n=0}^{k_n} \alpha_{nh_n} z^{y_{nh_n}} \right) \\ &= \sum_{h_1=0}^{k_1} \sum_{h_2=0}^{k_2} \dots \sum_{h_n=0}^{k_n} \left(\prod_{i=1}^n \alpha_{ih_i} z^{\varphi(y_{1h_1}, \dots, y_{nh_n})} \right) \end{aligned} \quad (13)$$

The polynomial $U(z)$ represents all the possible mutually exclusive combinations of realizations of the variables by relating the probabilities of each combination to the value of function $\varphi(Y_1, \dots, Y_n)$ for this combination.

In the case of MSS, u -functions

$$u_j(z) = \sum_{h_j=0}^{k_j} p_{jh_j} z^{g_{jh_j}} \quad (14)$$

represents the pmf of random performances of independent system elements. Having a generic model of an MSS in the form of equations (5) and (6) one

can obtain the measures of the risk by applying the following steps:

1. Represent the pmf of the random performance of each system element j in the form of the u -function (equation (14)).
2. Obtain the u -function of the entire system $U(z)$ that represents the pmf of the random variable V by applying the composition operator $\otimes_{\phi}$ that uses the system structure function ϕ (equation (6)).
3. Calculate the MSS performance indices applying equations (10) and (11) over system performance pmf (equation (7)) represented by the u -function $U(z)$.

While steps 1 and 3 are rather trivial, step 2 may involve complicated computations. Indeed, the derivation of a system structure function for various types of systems is usually a difficult task. As shown in [2], representing the structure functions in the recursive form is beneficial from the viewpoint of both derivation clarity and computation simplicity. In many cases, the structure function of the entire MSS can be represented as the composition of the structure functions corresponding to some subsets of the system elements (MSS subsystems).

The u -functions of the subsystems can be obtained separately and the subsystems can be further treated as single equivalent elements with the performance pmf represented by these u -functions. The method for distinguishing recurrent subsystems and replacing them with single equivalent elements is based on a graphical representation of the system structure and is referred to as the *reliability block diagram* method. This approach is usually applied to systems with a complex series–parallel configuration.

Generalized RBD Method for Series–Parallel MSS

The structure function of a complex series–parallel system can always be represented as a composition of the structure functions of statistically independent subsystems containing only elements connected in a series or in parallel. Therefore, to obtain the u -function of a series–parallel system, one has to apply the composition operators recursively to obtain the u -functions of the intermediate pure series or pure parallel structures.

The following algorithm realizes this approach:

1. Find any pair of system elements (i and j) connected in parallel or in series in the MSS.
2. Obtain the u -function of this pair using the corresponding composition operator $\otimes_\varphi$ over two u -functions of the elements:

$$\begin{aligned} U_{\{i,j\}}(z) &= u_i(z) \otimes_\varphi u_j(z) \\ &= \sum_{h_i=0}^{k_i} \sum_{h_j=0}^{k_j} p_{ih_i} p_{jh_j} z^{\varphi(g_{ih_i}, g_{jh_j})} \end{aligned} \quad (15)$$

where the function φ is determined by the nature of interaction between the elements' performances.

3. Replace the pair with single element having the u -function obtained in step 2.
4. If the MSS contains more then one element, return to step 1.

The resulting u -function represents the performance distribution of the entire system.

The choice of the functions φ for series and parallel subsystems depends on the type of system.

For example, in flow transmission MSS, where performance is defined as capacity or productivity, the total capacity of a subsystem containing two independent elements connected in series is equal to the capacity of a bottleneck element (the element with least performance). Therefore, the structure function for such a subsystem takes the form

$$\phi_{\text{ser}}(G_1, G_2) = \min\{G_1, G_2\} \quad (16)$$

If the flow can be dispersed and transferred by parallel channels simultaneously (which provides the work sharing), the total capacity of a subsystem containing two independent elements connected in parallel is equal to the sum of the capacities of these elements. Therefore, the structure function for such a subsystem takes the form

$$\phi_{\text{par}}(G_1, G_2) = G_1 + G_2 \quad (17)$$

In the task processing MSS, where the performance of each element is characterized by its processing speed, different subtasks are performed by different components consecutively. Therefore, the time for the entire task completion (reciprocal of the processing speed) is equal to the sum of subtask execution times. In terms of the processing speeds, one

can determine the performance of a subsystem consisting of two consecutive elements as

$$\begin{aligned} \varphi_{\text{ser}}(G_1, G_2) &= \text{inv}(G_1, G_2) \\ &= \frac{1}{1/G_1 + 1/G_2} = \frac{G_1 G_2}{G_1 + G_2} \end{aligned} \quad (18)$$

Parallel elements perform the same task starting it simultaneously. The task is completed by a group of elements when it is completed by any element belonging to this group. Therefore, the performance of the group is equal to the performance of its fastest available element. Therefore, for a subsystem of two parallel elements

$$\phi_{\text{par}}(G_1, G_2) = \max\{G_1, G_2\} \quad (19)$$

MSS Survivability and Optimal Defense

A survivable system is one that is able to complete its mission in a timely manner, even if significant portions are incapacitated by attack or accident. This definition presumes two important things.

First, the impact of both external factors (attacks) and internal causes (failures), affects system survivability. Therefore, it is important to take into account the influence of the availability of system elements on the entire system survivability.

Second, a system can have different states corresponding to different combinations of failed or destroyed elements composing the system. The success of a system is defined as its ability to meet a demand.

The damage caused by the destruction of elements with different performance rates will be different. Therefore, the performance rates of system elements should be taken into account when the risk associated with both the failures and the attacks is estimated. The index $R(\theta)$ (equation (8)) for the systems exposed to the external attacks is named *survivability*. The risk measure $1 - R(\theta)$ is named *system vulnerability*.

Any external impact can be considered as a common cause failure since several elements, not separated one from another, can be destroyed by the same impact. To evaluate the system vulnerability, one has to incorporate the common cause failures probability into the RBD method as suggested in [2, 4].

To reduce the system vulnerability, the elements can be separated (to avoid the destruction of several elements by a single attack) and protected.

Protecting against intentional attacks is fundamentally different from protecting against accidents or natural cataclysms [5]. Adaptive strategy allows the attacker to target the most sensitive parts of a system. Choosing the time, place, and means of attacks, the attacker always has an advantage over the defender.

Therefore, the optimal policy for allocating resources among possible defensive investments should take into account the attacker's strategy.

Unlike protecting against accidents or natural cataclysms, defense strategies against intentional attacks can influence the adaptive strategy of the attacker. This can be achieved not only by separation and protection of system elements, but also by creating false targets.

The three components of the defense strategy play different roles: deployment of the false targets reduces the probability of the attack on each separated group of elements, protection reduces the probability of elements getting destroyed in case of attack, and separation reduces the damage caused by a single successful attack. To evaluate the influence of the defense strategy components on the system vulnerability, one has to use the multistate model.

Examples of defense strategy optimization based on the universal generating function and the generalized RBD method can be found in [6–9].

GREGORY LEVITIN

Multivariate Reliability Models and Methods

There are several multivariate extensions of failure time distributions, hazard rate, positive and negative aging. In this paper, we generally consider those models that have no unique natural extension in the multivariate case. More specifically, for failure time distributions like exponential and Weibull, there is no unique natural extension. Exponential distribution plays an important role as failure time distribution with loss of memory property (LMP) and also in reliability theory. However, the multivariate extensions of exponential are not straightforward (*see Copulas and Other Measures of Dependency*). There are several versions of bivariate exponential (BVE) or multivariate exponential (MVE) distributions given by several authors. The main characteristics of BVE or MVE are (a) marginal exponential, (b) absolute continuity, and (c) LMP given by Marshall and Olkin [1]. At most, two of the three characteristics are satisfied by these BVE models. If all the three characters are satisfied, then it leads to independent exponentials. In a similar way, there are different generalizations of BVE to bivariate Weibull (BVW), Pareto, and extreme value distributions by transformation of variables.

Bivariate survival data arise when each study subject experiences two events. Failure times of paired human organs, e.g., kidneys, eyes, lungs, and the recurrence of a given disease are particular examples of such data. In a different context, the data may consist of time to diagnosis or hospitalization and the time to eventual death from a fatal disease. In industrial applications, these data types may come from systems whose survival depends on the survival of two very similar components. For example, the breakdown times of dual generators in a power plant or failure times of twin engines in a two-engine airplane are illustrations of bivariate survival data.

Marshall and Olkin [1] proposed a well-known BVE distribution which is widely accepted in the literature for reliability applications. The main characteristic feature of the Marshall–Olkin model (*see Mathematics of Risk and Reliability: A Select History*) is simultaneous failures occurring due to shock, which leads to dependence between the two components. In a similar manner, the characteristic feature

of the Freund [2] model is that the failure rate of the lifetime of a component changes when the other component fails, which is very common in real-life situations. When one component fails, there is a load on the other component and the failure rate of other survival time of the other component increases, which leads to the dependence between the two components. These two types of dependence structures are combined in the BVE of Proschan and Sullo [3].

The BVE models of Marshall and Olkin [1] and Freund [2] are the submodels of the BVE of Proschan and Sullo [3]. The BVE of Block and Basu [4] is the submodel of Freund [2] and also an absolutely continuous part of Marshall and Olkin [1]. The BVE of Marshall and Olkin [1] and Proschan and Sullo [3] are not absolutely continuous and they have a positive density on the diagonal $T_1 = T_2$. Lee [5] extended the BVE of Gumbel [6] to BVW by taking power transformation. Lu [7] extended the Weibull extensions to the Freund and the Marshall–Olkin BVE models. Later Hanagal [8] extended to the multivariate Weibull (MVW) distribution which is the extension of the BVW of Lu [7] and also an extension of the MVE of Marshall and Olkin [1]. Basu [9] extended the univariate failure rate to the bivariate case.

The LMP in the multivariate set up given by Marshall and Olkin [1] is as follows:

$$\begin{aligned} P[T_1 > t_1 + s, \dots, T_k > t_k + s] \\ &= P[T_1 > t_1, \dots, t_k > T_k]P[T_1 > s, \dots, T_k > s] \\ &\quad \times S(t_1 + s, \dots, t_k + s) \\ &= S(t_1, \dots, t_k)S(s, \dots, s) \end{aligned} \quad (1)$$

where $S(\cdot, \dots, \cdot)$ is the multivariate reliability function or multivariate survival function. The above equation is a weaker version of the multivariate LMP with common s . The stronger version is

$$\begin{aligned} P[T_1 > t_1 + s_1, \dots, T_k > t_k + s_k] \\ &= P[T_1 > t_1, \dots, T_k > t_k] \\ &\quad \times P[T_1 > s_1, \dots, T_k > s_k] \\ &\quad \times S(t_1 + s_1, \dots, t_k + s_k) \\ &= S(t_1, \dots, t_k)S(s_1, \dots, s_k) \end{aligned} \quad (2)$$

In the stronger version of LMP, only independent exponentials satisfy this property.

The reliability and risk assessment of the system is an integral element of the design process. To achieve greater reliability of the system, one has to minimize the risk with respect to quality of raw material, skilled manpower, precaution in event of catastrophe, robustness of the system, and several other factors. The risk function increases as the lifetime of the system increases or the reliability of the system decreases. The risk function is directly proportional to the lifetime and inversely proportional to the reliability of the system. The multivariate risk function (or multivariate hazard function) is related to the multivariate reliability function i.e., $H(t_1, \dots, t_k) = -\log S(t_1, \dots, t_k)$ where $H(t_1, \dots, t_k)$ is the multivariate risk function.

In the section titled “Frailty Models”, we discuss the frailty models in multivariate reliability models (see **Risk Classification/Life**). Frailty means unknown covariates. Frailty models are random-effect models and they follow certain distributions. They are used to reduce heterogeneity in the error term.

Frailty Models

The shared gamma frailty models were suggested by Clayton [10] for the analysis of the correlation between clustered survival times in genetic epidemiology (see **Insurance Applications of Life Tables; Default Correlation**). In a frailty model, it is absolutely necessary to be able to include explanatory variables with frailty or random effect. The reason is that the frailty describes the influence of common unknown factors. If some common covariates are included in the model, the variation owing to unknown covariates should be reduced.

Common covariates are common for all members of the group. For monozygotic twins, examples are sex and any other genetically based covariate. Both monozygotic and dizygotic twins share date of birth and common prebirth environment. By measuring some potentially important covariates, we can examine the influence of the covariates, and we can examine whether they explain the dependence, that is, whether the frailty has no effect (or more correctly, no variation), when the covariate is included in the model.

It is not possible, in practice, to include all relevant covariates. For example, we might know that some

given factor is important, but if we do not know the value of the factor for each individual, we cannot include the variable in the analysis. For example, it is known that excretion of small amounts of albumin in the urine is a diagnostic marker for increased mortality, not only for diabetic patients, but also for the general population. However, we are unable to include this variable, unless we actually obtain urine and analyze samples for each individual under study. It is furthermore possible that we are not aware that there exist variables that we ought to include. For example, this could be a genetic factor, as we do not know all possible genes having influence on survival. This consideration is true for all regression models and not only survival models. If it is known that some factor is important, it makes sense to try to obtain the individual values, but if it is not possible, the standard is to ignore the presence of such variables. In general terms, we let the heterogeneity go into the error term. This, of course, leads to an increase in the variability of the response compared to the case, when the variables are included. In the survival data case, however, the increased variability implies a change in the form of the hazard function, as is illustrated by some more detailed calculations.

The regression model is derived conditionally on the shared frailty (Y). Conditionally on Y , the hazard function for individual j is assumed to be of the form

$$Y\mu_j(t)$$

where $\mu_j(t)$ is the hazard function of the j th individual and it is assumed that the value of Y is common to several individuals in a group. Independence of lifetimes corresponds to no variability in the distribution of Y , implies that Y has a degenerate distribution. When the distribution is not degenerate, the dependence is positive. The value of Y can be considered as generated from unknown values of some explanatory variables. Conditional on $Y = y$, the multivariate survival function (see **Lifetime Models and Risk Assessment**) is

$$S(t_1, \dots, t_k|y) = \exp[-y\{M_1(t_1) + \dots + M_k(t_k)\}] \quad (3)$$

where $M_j(t) = \int_0^t \mu_j(u) du$, $j = 1, 2, \dots, k$ are the integrated conditional hazards. From this, we immediately derive the bivariate survival function by integrating Y out

$$\begin{aligned} S(t_1, \dots, t_k) &= E \exp[-Y\{M_1(t_1) + \dots + M_k(t_k)\}] \\ &= L(M_1(t_1) + \dots + M_k(t_k)) \end{aligned} \quad (4)$$

where $L(\cdot)$ is the Laplace transform of the distribution of Y . Thus, the bivariate survivor function is easily expressed by means of the Laplace transform of the frailty distribution, evaluated at the total integrated conditional hazard.

Gamma distributions have been used for many years to generate mixtures in exponential and Poisson models. From a computational point of view, gamma models fit very well to survival models, because it is easy to derive the formulas for any number of events. This is because of the simplicity of the derivatives of the Laplace transform. This is also the reason why this distribution has been applied in most of the applications published until now. For many calculations, it makes sense to restrict the scale parameter (θ) and shape parameter (α). The standard restriction is $\theta = \alpha$, as this implies a mean of one for Y , when $\alpha \rightarrow \infty$, the distribution becomes degenerate. The probability density function (PDF) of a gamma distribution with a single parameter (α) is as follows:

$$f(y) = \alpha^\alpha y^{\alpha-1} \exp(-\alpha y) / \Gamma(\alpha) \quad (5)$$

The Laplace transform of gamma is

$$E\{e^{-sY}\} = \left[1 + \frac{s}{\alpha}\right]^{-\alpha} \quad (6)$$

Hanagal [11] proposed the BVW regression models with gamma distribution as a frailty for the survival data and estimated the frailty parameter and also the parameters of BVW model.

In some situations, the gamma frailty model may not fit well. Hougaard [12] proposed a positive stable model as a useful alternative, in part because it has the attractive feature that predictive hazard ratio decreases to one over time. The property is observed in familial associations of the ages of onset of diseases with etiologic heterogeneity, where genetic cases occur early and long-term survivors are weakly correlated. The gamma model has predictive hazard

ratios, which are time invariant and may not be suitable for these patterns of failures.

The pdf of positive stable distribution with single parameter (α) is given by

$$\begin{aligned} f(y) &= \frac{1}{\pi} \sum_{k=1}^{\infty} \frac{\Gamma(k\alpha + 1)}{k!} \left(-\frac{1}{y}\right)^{\alpha k + 1} \sin(\alpha k \pi), \\ y &> 0, \quad 0 < \alpha < 1 \end{aligned} \quad (7)$$

with Laplace transform

$$E\{e^{-sY}\} = \exp(-s^\alpha) \quad (8)$$

Hanagal [13] proposed the BVW regression models with positive stable distribution as a frailty for the survival data and estimated the frailty parameter and also the parameters of the BVW model.

The power variance function (PVF) distribution is used as another alternative for frailty. It is a three-parameter family uniting gamma and positive stable distributions. Inverse Gaussian and noncentral gamma distributions are also submodels of the PVF distribution.

Yashin and Iachine [14] developed correlated frailty models for the analysis of bivariate failure time data, in which two associated random variables are used to characterize the frailty effect for each pair. For example, one random variable is assigned for partner 1 and one for partner 2 so that they would no longer be constrained to have a common frailty. These two variables are associated and have a joint distribution. Knowing one of them does not necessarily imply knowing other. Examples of the use of multivariate frailty models are various and are listed below.

1. Aalen and Tretli [15] analyzed the incidence of testis cancer by means of a frailty model based on data from the Norwegian Cancer Registry collected during 1953–1993. The incidence of testicular cancer is greatest among younger men, and then declines from a certain age. The frailty is considered to be established by birth, and due to a mixture of genetic and environmental effects. The idea of the frailty model is that a subgroup of men is particularly susceptible to testicular cancer, which results in selection over time. This would explain why testis cancer is primarily a disease of young men. Aalen and Tretli [15]

applied the compound Poisson frailty distribution to testicular cancer data.

2. Malignant melanoma (skin cancer) was studied at the University Hospital of Odense in Denmark. Hougaard [16] compared the traditional Cox regression model with a gamma frailty and PVF frailty model, respectively to these data.
3. An example deals with the time from insertion of a catheter into dialysis patients until it has to be removed because of infection. A subset of the complete data, including the first two infection times of 38 patients, was published by McGilchrist and Aisbett [17] who used lognormal frailty model. To account for the heterogeneity within the data, Hougaard [16] used a gamma frailty model.

DAVID D. HANAGAL

Natural Resource Management

Risk assessment for natural resource management (NRM) deals with the *uncertainty* of our *impact* on the natural environment. Economic growth, development, and individual prosperity generally occur at the expense of environmental conservation and protection. The world's population is about 6.5 billion [1] and at its present rate of growth, will hit 10 billion by 2040. This will create unprecedented pressures on an already stressed environment. The realization that rates of consumption of even so-called renewable resources outstrip rates of production has been slow in coming. Actions to halt or reverse the trend have been even slower. The Central Intelligence Agency (CIA) [1] identifies rapid depletion of nonrenewable mineral resources, depletion of forests and wetlands, plant and animal extinctions, and the deterioration of air and water quality as among the most serious long-term environmental problems (*see* **Air Pollution Risk; Water Pollution Risk**). Human-induced climate change ranks as perhaps the single most pressing issue confronting mankind (*see* **Global Warming**). While degrading the environment, we simultaneously seek continuity of "ecosystem services" from it. Our list is long. We want clean air, rivers, streams, oceans, estuaries lakes, coasts, aquifers, and soil. We want safe, reliable, and clean supplies of drinking water and food. And we want our human, industrial, and household wastes to be disposed of safely (but "not in my backyard") while ensuring habitat and species conservation, environmental restoration, long-term sustainability, no adverse impacts on human health, and a full and comprehensive assessment of risks (*see* **Hazardous Waste Site(s); What are Hazardous Materials?**). Clearly, there are trade-offs that need to be acknowledged and balances that need to be struck.

Strategies that aim to reconcile economic growth and development with sustainability and environmental impact are characterized by risk. There are a number of facets to the risk equation: (a) uncertainty in all its forms (epistemic, linguistic, model); (b) model incertitude – how do we formulate and calibrate models to describe events that have never occurred and for

which no data are available? – and (c) natural variability. Furthermore, as with any modeling approach, risk assessments may be compromised by an inability or reluctance to enumerate all possible consequences (e.g., the effects of smoking on humans was known by tobacco companies, but not revealed, while the effect of polychlorinated biphenyls (PCBs) in the environment only became evident years after they were first used). Other issues also arise, such as how to assess the quality of different risk assessors and different estimates and predictions (e.g., in 1968 Paul Ehrlich claimed millions of people would starve to death because of overpopulation [2], while Galtung [3] concluded that "experts . . . were remarkably wrong" in their predictions) and the difficulty in answering the question "how well did we do" after adopting a risk-based approach to environmental decision making.

To manage natural resources and assets is to manage risk. For example, we build dams to guarantee water supply, but do so at the risk of decreasing biodiversity, altering in-stream species composition, and affecting riparian vegetation further downstream. The omnipotent threat of climate change and climate variability only serves to increase uncertainties and exacerbate consequences. Thus, in countries such as Australia where climate change has resulted in prolonged droughts, the level of uncertainty in water resource management is extraordinarily high. The accurate quantification of natural resources is central to a risk-based approach to NRM, as is the provision of reliable estimates of variability and uncertainty in these estimates. This, it is acknowledged, is easier said than done because reliable quantification, estimation, and prediction for natural resource management is rendered particularly difficult by virtue of two important characteristics of natural systems: complexity and uncertainty. Complexity arises from highly nonlinear relationships, feedback loops, hysteresis, multiple causes and effects, and timescales ranging from fractions of a second to millions of years. On the other hand, uncertainty in natural systems is often the result of one or more of the following factors: an event whose consequences are predictable (e.g., flood, drought, earthquake), but whose timing and magnitude are not; a discontinuity in an otherwise smooth trend (e.g., rapid change in pH when the buffering capacity of a water body is exceeded); or, as we have

already noted, unanticipated consequences of deliberate actions.

Traditional compliance-based approaches to pollution control focus on setting environmental standards whereby “safe” concentrations, loads, or exposure levels were identified and used as a not to be exceeded, regulatory limit. The approach focused on limiting public exposure to specific pollutants and did very little to identify pollution prevention measures that prohibit whole families of dangerous pollutants from being produced in the first place [4]. As noted by Fox [5], this resulted in data rich–information poor environment protection agencies that were ill equipped to make more comprehensive and holistic assessments of the environment. During the 1980s, risk-based approaches to NRM became increasingly popular, although as noted elsewhere in this encyclopedia (*see Ecological Risk Assessment*), these approaches were hampered by a lack of agreement as to what actually constituted a risk assessment, imprecise language, and inconsistent modes of analysis and application of risk methodologies.

Setting Environmental Standards for NRM

NRM encompasses environment protection, but has a broader scope. It is about balancing competing risks and demands, while ensuring the long-term sustainability of the biosphere or some part of it. The duality between *management* and *protection* has resulted in the establishment of environmental standards. The “fixed lines in the sand” that characterized the command-and-control approach to environmental regulation in some areas of NRM have given way to more flexible “standards”, “guidelines”, and “trigger values”. This has been necessary because high levels of complexity, uncertainty, and background variation mean that transgressions of fixed lines will occur even in the absence of anthropogenic influences. For example, storm events often result in exceedingly high concentrations and loads of sediments and nutrients in rivers and streams; upwelling in oceans may be responsible for abnormally high chlorophyll levels at the surface; while complex population dynamics may result in uncharacteristic abundances of some (nuisance) species that are unrelated to human impact. The important feature of a standard, guideline, or trigger value is that it is not so much the “violation” of the numerical target that is important,

but rather the *frequency* with which such violations occur. This notion immediately moves us away from prosaic “in compliance–out of compliance” assessments and more into the realm of *risk*. As noted by Barnett and O’Hagan [6], management standards need to be set in the context of an understanding of the processes involved and not the result of a somewhat arbitrary scaling of a result adapted from elsewhere. For example, prior to the release of revised water quality guidelines [7], many threshold values for pollutants and toxicants in marine and freshwaters were established using the “assessment factor” technique. Using this procedure, an endpoint (i.e., some outcome of a toxicity experiment) concentration for an organism or animal was scaled by a “factor” – typically orders of magnitude (10, 100, 1000 etc.) – so as to provide a margin of safety for humans. Notwithstanding the arbitrariness associated with the choice of the numerical factor value, no consideration was given to how relevant, meaningful, or achievable the resulting concentration was (*see Cumulative Risk Assessment for Environmental Hazards*). Nor did it provide any quantification of the level of protection afforded to humans and other species. In recognition of these deficiencies, the Australian guidelines adapted the risk-based approach of Aldenberg and Slob [8]. The idea was to use a theoretical distribution fitted to a sample of no observable effect concentrations (*NOECs*). This is the smallest concentration at which an “effect” (in terms of a designated endpoint) is observed from which a small percentile (typically 5%) was estimated. The resulting figure is referred to as a *trigger value* since an exceedance does not result in punitive action but rather it triggers a next-level investigation to explain why such a result was observed. A distinguishing feature of the trigger value is its attempt to tie the concentration to an effect in the population. The underlying assumption that a trigger value obtained as the p th percentile from the *NOEC* distribution will be protective of $p\%$ of all species in the environment is, nevertheless, contentious [9].

NRM, the Precautionary Principle, Neyman–Pearson Hypothesis Testing and Statistical Power

Countries around the world have, to varying degrees, embraced the *Precautionary Principle* (PP) as a guiding philosophy for risk-based NRM. A number of

variants of the PP exist; however, the basic tenet is that it seeks to avert or limit the risk of serious or irreversible harm to humans or the environment in the absence of full scientific certainty about that harm [10]. The critical issue is not whether we should be precautionary, but how precautionary we need to be on a case-by-case basis [11]. Poor risk management arises not only from insufficient levels of precaution, but equally from the pursuit of excessively high and unwarranted levels of precaution [11]. As we have seen in earlier sections of this article, uncertainty is a hallmark of NRM. The PP is one approach to dealing with uncertainty. A number of others exist such as prudent reduction, principle of prevention, best available techniques not entailing excessive cost (BATNEEC), best practicable environmental option (BPEO), and as low as reasonably achievable (ALARA). A distinguishing (and contentious) feature of the PP is that it shifts the onus of proof. Under the PP, proponents of a proposed activity (e.g., construction of a dam, erection of a mobile phone tower, deepening of a shipping channel, logging of a forest, construction of a housing estate) may be required to demonstrate that the activity has no serious or unacceptable environmental or human-health implications. Historically, the burden of proof has required those *opposing* the proposed activity to demonstrate that the activity is harmful. It is at this juncture, that risk assessments are usually produced in support of diametrically opposed conclusions. Statistical models can assist, although the use of different data and different modes of analysis are just two reasons behind the confusion and controversy that often accompanies a formal quantitative risk assessment (QRA). Conventional statistical hypothesis testing (or *null hypothesis testing* (NHT), as it is sometimes referred to), commences with a pair of hypotheses. The *null hypothesis* (“null” because it is meant to assume nothing or status quo conditions) is initially assumed to be true; the *alternative hypothesis* is generally the compliment or negation of the null hypothesis and will only be adopted if the evidence (in the form of data) provides extremely low support for the null hypothesis. This level of support is embodied in the ubiquitous (and widely misunderstood and abused) *p value*. The declaration of a “statistically significant result” occurs when a statistical test procedure returns a “small” *p value*. In the context of NRM, many of these features of hypothesis testing are troublesome. For a start, how small is small when

it comes to *p values* and who decides? why is the minimization of a Type I error (the probability that the test incorrectly rejects a true null hypothesis) seen to be overwhelmingly more important than the minimization of a Type II error (the probability that a false null hypothesis is accepted)? is it sensible to adopt the convention of couching a null hypothesis in terms of “no effect” when applied to NRM? and finally, is the binary view of the world that the hypothesis testing framework imposes on us the best way to assess environmental condition? Notwithstanding these issues, the PP imposes a role reversal on the null and alternative hypotheses. A precautionary approach to hypothesis testing would commence with an hypothesis that asserts that the proposed action has deleterious consequences. The alternative hypothesis then states that the consequences are not deleterious. As with the PP, this hypothesis testing schism has no clear-cut solution or recommendations although Fox [12] provided details of a hybrid approach. Equally problematic is the issue of “ecological significance” – that is, quantifying the magnitude of a change in condition that would be ecologically important. Environmental scientists and natural resource managers often struggle with the specification of an ecologically important effect size, but this is mandatory if, as is increasingly being demanded by natural resource management agencies, the issue of *statistical power* is to be investigated.

Statistical power and sample size analyses are useful adjuncts in the *planning* stage of any investigation or study. An *a priori* power analysis requires the investigator to nominate an ecologically significant effect size, a measure of intrinsic variation in the parameter under study (usually a mean response), a sample size and a level of significance (the Type I error rate). Armed with this information, it is a fairly straightforward task to compute the probability that the hypothesis-test procedure will correctly reject a false null hypothesis. This probability is referred to as the *power* of the statistical test. Obviously, a test with high power is preferred over a low-powered test. Unfortunately, further confusion exists about how to calculate and interpret the results of a power analysis. This is hardly surprising, given the lack of consensus in the literature and the publication of flawed advice [13, 14]. In fact, Hoenig and Heisey [15] identified 19 independent articles published between 1983 and 1997 advocating the

use of *postexperiment* power analysis. Postexperiment power analysis often involves the computation of “observed power” – a flawed quantity which will invariably “explain away” a nonsignificant statistical result as an outcome of a low-powered statistical design.

Modes of Analysis: Frequentist or Bayesian

Until recently, quantitative risk analyses were underpinned by “conventional” modes of statistical analysis. Frequentist statistical inference makes up the bulk of all statistical methodology and undergraduate statistics courses devote considerable time to it. Neyman–Pearson hypothesis testing and regression techniques are the mainstays of environmental assessments that support natural resource management decisions. There is nothing intrinsically wrong with these methods. Provided the attendant assumptions are satisfied, conventional *t-tests* and analysis of variance (ANOVA) techniques are optimal (uniformly most powerful) – in other words, one can essentially do no better with the available resources. Unfortunately, although diagnostic analyses are available to help assess the adequacy of the statistical method employed, these are oftentimes overlooked or ignored. This is seen as a major shortcoming of current NRM risk analyses. The inappropriate use of statistical models can result in fatally flawed natural resource management decisions.

Frustrated with actual and perceived limitations of the frequentist dogma, many environmental scientists are turning to information theory [16] and *Bayesian statistics* [17] (see **Bayesian Statistics in Quantitative Risk Assessment**) as alternative paradigms that are more aligned with the goals of risk-based NRM. Bayesian methods are seen as attractive if for no other reason than an explicit recognition of the legitimacy of “subjective” probability in the form of a *prior* probability distribution. In the context of NRM, a prior probability distribution might, in fact, represent the diversity of (personal) belief about some proposition that is held by a range of stakeholders. Although this does not necessarily mean that a Bayesian approach is necessarily superior to other competing methodologies, it does have a certain appeal, inasmuch as it provides a transparent means of elicitation and incorporation of personal belief and/or expert opinion. To this extent, Bayesian

methods are useful and are being increasingly used as part of a risk-based approach to NRM decision making.

As noted by Schipper and Meelis [18], data used to underpin decisions about environmental condition are invariably collected successively in time and so it makes sense to analyze those data sequentially. Apart from their own work, relatively little seems to have been done along these lines.

Future Directions

An examination of the literature identifies follow-up monitoring as a significant gap in risk-based approaches to NRM. Thus, while we argue over the merits of the precautionary principle and the commensurate shift toward prudent foresight, we spend comparatively little time on asking “how well did we do” [19, 20]. As noted by Suter [21], “a common criticism of risk-based environmental management is that we do not know whether it is effective”. Further research is required to develop companion tools and techniques that allow risk assessors to gauge the effectiveness of individual risk-based NRM programs.

As noted in this article, Bayesian methods for risk-based NRM are becoming increasingly popular. Protocols for the elicitation of “expert opinion” require further development and refinement as do methods for ranking those opinions. This may require closer collaboration between psychologists and statisticians to develop methods for reliably extracting opinions to improve the quality of the risk analysis and increase stakeholder trust in the process.

Acknowledgment

The author acknowledges the helpful advice of an anonymous referee and Prof. Mark Burgman at the University of Melbourne for his thoughtful comments on an earlier draft of this article.

Near-Miss Management: A Participative Approach to Improving System Reliability

In this article, the authors discuss the “near-miss” concept, present various definitions used in different settings, and illustrate the utility of the concept by giving examples of where near-misses are used for evaluation of a system’s risk potential. We then identify the important constituents of a near-miss management system (NMMS) to achieve a high level of effectiveness.

The “Near-Miss Concept”

The notion of a “near-miss” (*see Operational Risk Modeling*) can best be explained by observations made in the process industries. When adverse incidents have occurred, it is observed that for every serious accident, a large number of related prior incidents occurred that resulted in limited impact and an even larger number of related prior incidents happened that resulted in no loss or damage. This observation is captured in the well-known safety pyramid shown in Figure 1 [1], which has been substantiated by many examples.

Incidents at the pyramid pinnacle, referred to in this chapter as “accidents”, may result in injury and loss, major environmental impact, and/or significant business disruption. These incidents are often obvious, are brought forcefully to the attention of management, and are reviewed according to site protocols. “Near-misses” comprise the lower portion of the pyramid. These incidents, depending on the circumstances, either result in minor losses or have the potential for but do not result in a loss. Near-misses are often less obvious than accidents and are defined as having little, if any, immediate impact on individuals or processes. Near-miss concept covers a broad range of incidents. Although in most cases it is not difficult to differentiate between a near-miss and an accident, under some conditions, such as an adverse event with a considerable negative impact, an incident can be classified either as an accident or as a near-miss. Such uncertain conditions are indicated by

the overlap region in Figure 1 and can be handled by procedures designed either for accidents or for near-misses.

Despite their limited direct impact, near-misses provide insight into potential accidents that could happen. Therefore, near-misses can be considered “indicators of potential problems”, including those of system flaws. The following are examples of near-misses signaling system issues:

1. Identification and reporting of O-ring degradation and its direct link to takeoff temperature of the Space Shuttle Challenger were noted as early as 1982, well before its explosion in 1986 [2].
2. Identification and written reporting of corroded and leaking pipes were noted well before they caused the 1997 Hindustan refinery explosion, resulting in the death of 60 people and atmospheric release of 10 000 metric tons of petroleum-based products [3].
3. Reporting of eight “signals passed at danger” (SPAD) between 1993 and 1999 for Signal 109 was recorded before the Paddington train crash in England in which 31 people died [4].

Within the last decade, several new disciplines have accepted the “near-miss” concept as a tool to improve the reliability of risk management systems. Tracking near-misses enables the early identification of “risk” and provides an opportunity to mitigate potential losses. In this work, near-misses across different industries, and a variety of service operations and natural disasters, have been considered. In the process, differences in near-miss definitions and the utilization of near-miss approaches to assess and manage a system’s risk factors have emerged and have been evaluated. Industrial near-misses are defined as events with minimal consequences. In case of natural disasters, such as seismic events, hurricanes, floods, drought, heat waves, etc., near-misses are defined as events that nearly gave rise to a major catastrophe. For example, a hurricane that missed a highly populated region and damaged the environment in a neighboring unpopulated area can be considered as a near-miss from which regional governments can learn the damage potential and take necessary precautions to minimize consequences in the future.

Some of the events that near-misses are associated with are more controllable, such as designing a

Figure 1 Safety pyramid (the lowest strata, unsafe conditions, is not shown by Bird and Germain) [Reproduced from [1] with permission from Det Norske Verita. © 1996.]

safer chemical process or a toy for a child, while others, such as hurricanes and earthquakes, cannot be controlled, but can be mitigated through various precautions designed and implemented in advance.

To reduce the likelihood of future accidents and to reduce system risk and improve process reliability, management and engineering systems that recognize operational weaknesses are being developed to seek and utilize accident precursors [5]. These programs operate under the umbrella of NMMS [6].

Although intensity and degree of control of events vary among different fields, the results of comparative analysis conducted using a wide selection of near-miss/accident data have shown significant similarities. Duffey and Saull [7] carried out an extensive study to examine the national and international reported error, incident, and fatal accident rates for multiple modern technologies, including shipping losses, industrial injuries, automobile fatalities, aircraft events and fatal crashes, chemical industry accidents, train derailments and accidents, medical errors, nuclear events, and mining accidents. Data for a time span of 20–200 years were collected and it was shown that all of the error data of different technologies follow a universal learning curve. That is to say, high error rates decline and are reduced exponentially to a minimum level as learning experiences (i.e., data) are accumulated.

The following examples are used to (a) demonstrate a variety of applications where near-misses are utilized, (b) identify influence of various stressors on the near-misses, and (c) understand the culture and functionality of the field to alter the key parameters that influence frequencies and consequences of

near-misses. Ashcroft *et al.* [8] conducted an analysis of dispensing errors and near-misses occurring in 35 community pharmacies in the United Kingdom, and concluded that for every 10 000 items dispensed, there are around 22 near-misses, and 4 dispensing errors. In another healthcare study, McDonald [9] analyzed near-misses arising from bar-coding systems in hospitals to improve patient safety. A national reporting system has been launched to examine the near-misses faced by fire fighters, and to improve their education, operations, and training [10]. Clarke *et al.* [11] performed a survey of 2287 nurses of medical surgical unit in 22 hospitals of United States and concluded that high workloads and poor organizational climates in hospitals cause increases in needle-stick injuries and other near-miss incidents affecting hospital nurses. Goldenhar *et al.* [12] analyzed near-miss and injury data for construction workers and examined their relationship with various job stressors (for example, job demand, training, safety climate, and exposure hours). Lilley *et al.* [13] examined the impact of organizational changes in the New Zealand Forestry Industry on the near-misses and accidents faced by forestry workers.

An NMMS helps to improve process reliability and reduce business risk. Muermann and Oktem [14] proposed using the “near-miss” concept as an advanced management approach for operational risk in financial institutions. In another study, Tucker and Spear [15] studied six US hospitals to examine the frequency of work system failures and their impact on nurse productivity. The five most common failures involved medications, orders, supplies, staffing, and equipment. They suggested that nurses’ effectiveness

can be increased by creating improvement processes to remediate the work system failures identified by near-misses.

A recent example that demonstrates how identification and management of near-miss could have saved significant business losses is the Sony battery recall case. Although Sony was made aware that there were some overheating issues in laptop computers as early as October 2005 and February 2006, they did not order a recall and continued using previously stocked batteries. This was clearly a near-miss, which was ignored by Sony. Later, Sony batteries were identified for potential incidents in Dell laptops, which then led to battery recalls, causing a 96% decrease in Sony's reported quarterly net profit. Even at this point, they could have treated the Dell incident as a near-miss (although clearly with more significant impact) and recalled the batteries from other companies like Fujitsu, Toshiba, Gateway, Dell, and Apple, all of whom were users of Sony batteries. However, the company continued to miss the signals from these early near-miss incidents, and, ultimately, the problems were revealed in other companies as well. Estimates indicate that this problem will cost Sony at least \$429 million before it is resolved, and possibly twice as much when the results of legal actions are considered. Sony could have avoided much of this expense and business risk had they recalled the batteries when they originally observed the overheating issues (near-misses). The dynamics of this case study illustrate the power and advantages of having an NMMS in place and demonstrate the tremendous negative outcome of not dealing with near-misses in a systematic way early on [16–18].

The identification and management of near-misses have many dimensions. Some events clearly test the limits of the near-miss concept. For example, Cunningham [19] analyzed a chemical spill of cyanide and heavy metals from a gold processing plant in 2000, which quickly moved from one river to the next through Romania, Hungary, the Federal Republic of Yugoslavia, and Bulgaria, killing tens of thousands of fish and other forms of wildlife, as well as poisoning drinking-water supplies. This case demonstrates the importance of information flow and interpretation of events. While the spill was considered a disaster by some, it was seen as a nonevent by others. This suggests that precursor events can go unnoticed or be viewed as catastrophic, or anything in between,

depending upon political, historical, and personal perspectives and awareness.

In the literature, there are only a limited number of publications that quantitatively demonstrate the impact of an NMMS to reliably identify risks and reduce the number of “accidents”. Jones *et al.* [20] provided an account of NMMSs successfully applied in the European chemical industries. Two examples of “near-miss” programs applied at Norsk Hydro's offshore and onshore facilities were studied. In both cases, their results suggest that an increase in near-miss reports can yield improved safety performance. In offshore drilling, over 7 years, a 10-fold increase in near-miss reporting corresponded to a 60% reduction in lost-time injuries. In onshore activities, over a 13-year span, an increase in reporting rates from zero to one-half per person per year corresponded to a 75% reduction in lost-time injuries [21]. When the authors discussed this issue with different corporate representatives, they found that in general there is hesitation toward reporting near-miss data due to possible legal ramifications.

Near-Miss Management Systems

NMMSs are designed to enable people and institutions to learn from high-frequency, low-impact incidents (near-misses) to prevent low-frequency, high-impact incidents (accidents). Near-misses are considered “weak signals”, some of which contain the signature of more serious, adverse effects. Hence, near-misses provide insight into potentially major, harmful conditions and business disruptions. Therefore, addressing near-misses in a timely and disciplined manner reduces the frequency and consequences of larger problems [20].

Phimister *et al.* [21] proposed a seven-step NMMS on the basis of an extensive research in the chemical industry. This was modified further by Muermann and Oktem [14] into an eight-step process by separating one of the important functions, “prioritization”, from the others. These eight steps are as follows:

1. identification (recognition) of a near-miss;
2. disclosure (reporting) of the identified information/incident;
3. prioritization and classification of the information for future actions;
4. distribution of the right level of information to the proper channels;

5. analysis of causes of the problem;
6. identification of solutions (remedial actions);
7. dissemination of actions to the implementers and (optional) to a larger group for their knowledge;
8. resolution (wrap-up) of all open actions and completion of reports.

Implicit in the above structure of near-miss reporting and analysis is the value associated with NMMS arising at two levels. First is the sequencing itself. The sequential structure of the above eight-step process underlines the fact that achieving maximum potential learning from near-misses requires the successful execution of each progressive stage. Thus, logically, near-misses that are not identified will not yield any value. Near-misses that are not disclosed may lead to some value for local operators, but will not yield any broader lessons unless these near-misses are analyzed and the information is distributed. This chain of implications led to the eight-step model that reflects the fact that early steps in the NMMS have “conjunctive” or multiplier effects on later steps. Second level of value associated with NMMS arises from the proper execution of each step itself. Such that near-misses that are recognized can have an immediate benefit at that site, as increasing awareness and initiating precautionary measures to prevent similar events, even if they are not reported, analyzed, and disseminated further. The following discussion is provided to clarify the nature and value of each of the eight steps.

Step 1: Identification

The first step of any NMMS is the recognition of a near-miss. As mentioned previously, near-misses are defined in a variety of ways by different authors [14, 21, 22]. Some definitions are very focused and are based on the extent of the potential negative consequences, such as “a near-miss is an undesired event or sequence of events with potential to cause serious damage”. To make the near-miss experience an occasion to learn from and to improve, rather than a punishable event, it is better to use a broader definition which balances the negative side of near-misses by focusing also on their positive contributions to risk reduction and system reliability. The following is a definition, similar to the ones used by Phimister *et al.* [21] and Muermann and Oktem [14] which fits to the above criteria of emphasizing the positive contribution of a near-miss:

A near-miss is an event, a sequence of events, or any other opportunity, such as an observation, that has the potential to improve system reliability.

This definition contains three important features of a near-miss:

- It views near-misses as improvement opportunities, which are positive experiences encouraging employees to report rather than to hide these events.
- It not only captures events but also includes observations.
- It includes all disturbances, from those which have the potential to cause serious damage to others that are inconveniences or elements of system operation or configuration that mainly cause inefficiencies.

It is important that each company develop its own near-miss definition and clearly communicate it to its employees to eliminate any confusion. The authors’ earlier studies indicate that not being able to recognize an incident as a near-miss is one of the primary reasons for lack of reporting. While the above broad definition is appropriate for certain risks, such as operational risk in financial institutions or in information technology, a much more focused definition may be necessary for a specific process industry. Tamuz *et al.* [23] examined the effect of definition and classification of safety-related events in hospitals on the organizational routines for gathering information, allocating incentives, and analyzing reported data. Their study suggests that better definition and classification procedures may help in improving patient safety, given the processes specific to patient management.

Step 2: Disclosure

The reporting of a near-miss should be made very simple to encourage everyone who observes or experiences a problem to fill out a report without spending much time and effort. Bridges [24] focused on barriers that inhibit disclosure. To increase report rates, Bridges advocates that nine barriers be overcome. These can be grouped into the four categories listed below:

1. potential recriminations for reporting (fear of disciplinary action, fear of peer teasing, and investigation involvement concerns);

2. motivational problems (lack of incentive and management discouraging near-miss reports);
3. lack of management commitment (sporadic emphasis and management fear of liability);
4. individual confusion (confusion as to what constitutes a near-miss and how it should be reported).

Classification and interpretation of near-misses during disclosure is very important for overall effectiveness of an NMMS and should be given special attention during its development. For example, a shared near-miss event reporting system has existed in the aviation industry for over 25 years [25] and was signaled as a model to improve healthcare safety. At first glance, both industries have a lot in common, such as highly trained professionals who work in teams and use technology that can also be a factor in undesirable outcomes. But, Tamuz and Thomas [26] argue that although some aspects of aviation safety systems are readily transferable to healthcare, other aspects, including professional controls and organizational complexities, can differ significantly, thereby influencing event classification and interpretation. If these differences are not properly accounted for, potentially dangerous events may not be recognized even if a shared system is established.

The structure of reporting systems plays a very important role in implementation of this step. During our studies of the chemical industry, the authors observed that having two separate reporting mechanisms, one for near-misses and another for accidents, causes confusion, and hence, misreporting of incidents that could potentially be classified in both categories (see Figure 1). On the other hand, having a single reporting mechanism, which is usually geared for accidents and requires extensive information, becomes too cumbersome for most near-misses, discouraging people from reporting small incidents. A possible solution is to have a single reporting system which enables the reporter to differentiate between various levels of information requirements based on the nature of the incident. This can be achieved through guidelines and reporting criteria defined by the risk management group of an institution.

Step 3: Prioritization

Although investigations have shown that almost all major incidents had precursors with minor or no consequences, not all minor incidents have the potential

to cause major accidents. Yet the abundance of minor incident reports creates a prioritization dilemma. An effective near-miss system should average at least one or more near-miss reporting per person per year. In a large organization or an industrial site, this may result in thousands of near-misses that need management's consideration. If the same intense attention is paid to every detail of each near-miss, then the cost of the NMMS will be overwhelming and unsustainable. In contrast, if very little attention is given to each near-miss, the major problems brewing in the system will be missed. Therefore, prioritization is a very critical step in establishing an effective near-miss system since this step determines, out of the large number of near-miss reports, which ones will require, and to what extent, the attention of the limited resources assigned to near-miss management.

NMMSs must identify criteria to enable such classification. Guiding principles for such a classification must be determined at the corporate level and further defined at application sites and local levels. It is important to monitor the system initially until a thorough understanding of the prioritization criteria is established among the employees, since they will, most likely, determine the priority at the time of disclosure. Training programs can play a very important role in accomplishing this objective.

Step 4: Distribution

There are two objectives of this step:

1. to inform those who will provide the right level of follow-up and
2. to alert a broader audience of the hazard.

Once near-miss information is reported into the NMMS, it should be directed to those who can act upon it. Identification of the right recipients strongly depends on the design of the "priority" system mentioned above.

Common obstacles that limit the effectiveness of this stage include unwillingness of supervisors to share near-miss information and systems that do not specify a time frame for review.

Step 5: Analysis

Once a near-miss is reported on the basis of the given priority, the reporting party, a supervisor, or a group

of experts related to the subject matter should identify direct and root causes of the problem to arrive at action(s) to eliminate the recurrence of this or similar incidents. The objective in root-cause analysis (*see Canonical Modeling; Reliability Integrated Engineering Using Physics of Failure*) is to determine the direct and underlying factors of an incident or unsafe condition. Short-term solutions resolve direct causes, while more permanent solutions rectify root causes. When structuring near-miss programs, it is important to recognize both the interaction between root-cause analysis and solution determination, and the separateness of these activities. Following are examples of analysis found in the literature.

Uth and Wiese [27] studied the accident reports collected by a German central organization created in 1993 which is called as a central body for collecting and evaluating major accidents (ZEMA). In 1994, they extended their charter to analyze minor and near-miss events as well, realizing that the analysis of incidents, and not just accidents, was also important. The root-cause analysis of the data revealed the importance of maintenance, detailed knowledge of chemical properties, and human factor issues as possible areas upon which to focus to improve system safety and reliability.

Ebright *et al.* [28] carried out an analysis of near-misses and adverse events faced by novice nurses. In some cases, novice nurses were unable to prevent near-miss/adverse events because of the lack of information to manage the entire situation and their inability to sort out the relevant data to act upon.

Weeks *et al.* [29] analyzed 30 near-miss maternal cases in Uganda. They found that financial barriers, problems with transportation, medical mistakes, and delays in referral in rural health centers were the socioeconomic causes behind maternal problems that, in some cases, led to mortalities. Analysis of near-misses is especially valuable in this context because of the difficulty in understanding the facts that led to the mortalities. This is unlike the process industries where electronic information is often available, describing the sequence of events, before an accident.

Step 6: Solution Identification

Once the causes of a problem are identified, the next step is to find viable solutions for each cause. Important considerations to factor include the following:

1. Solutions should be matched to causes, thus making sure that each cause has been addressed.
2. If possible, a member of the department who will implement the solution under discussion should be included in solution identification.
3. Identified solutions should be reviewed to ensure that they will not cause new problems.

This third item, which is called *change management* in some industries, is of particular relevance. For example, McDonald [9] showed that bar-coding systems established in hospitals to improve patient safety can create new errors, when not accompanied by well-designed cross-check processes and second-level human confirmations.

The overall goal of this step is to ensure that the right solutions are identified for the differing organizational needs. For example, Yacavone [30] analyzed mishaps in naval aviation from 1986 to 1990. A significant fraction of mishaps were due to aircrew errors and were related to human failure. As a result, aircrew coordination training (ACT) was instituted to address issues of human error (*see Reliability Data; Human Reliability Assessment; Probabilistic Risk Assessment*). Wiegmann and Shappell [31] examined the role of human error and crew–resource management failures in the United States. Naval aviation mishaps between 1990 and 1996. Approximately 56% of mishaps involved at least one crew–resource management failure and a large fraction of these occurred during nonroutine or extreme flight. These trends did not change even after implementation of ACT, indicating that the solutions have to be tailored and, if necessary, modified to specific problems that are faced in order to be most effective.

Step 7: Information Dissemination

Once an action (or set of actions) is determined,

1. it should be approved by the proper channels and assigned to a group to implement;
2. a larger group, including other divisions of the organization, customers, etc., may need to be informed of the incident and the actions taken.

An example of the latter is “Dear Doctor” letters that pharmaceutical companies send to physicians when they find a potentially negative effect associated with an already marketed drug and seek to warn them

about changing their practice (its dose, combined use with another drug, etc.) with respect to this particular application.

Step 8: Resolution

In the final step, all actions are completed including follow-up with proper departments and individuals. This means identification and tracking of all open actions and their follow-up with the right people for their closure. These activities may involve seeking approval from higher management ranks to obtain priority for implementation procedures. It is also highly desirable and rewarding to give feedback to the individual who identified the near-miss and/or reported it. Action-tracking software packages are available on the market and can be purchased separately, if tracking is not already built into the existing NMMS.

There are several variations of NMMSs that exist in different industries. For example, Dye and van der Schaaf [32] discuss a near-miss reporting system to manage the risk of customer dissatisfaction in the telecommunication industry, titled “Prevention and Recovery Information System for Monitoring and Analysis (PRISMA)”. In this context, events leading to customer loss due to dissatisfaction are considered as accidents that are injurious or damaging to the business relationship, while customer complaints are considered to be near-misses. The seven steps of PRISMA are detection, selection, description, classification, computation, interpretation and implementation, and evaluation. PRISMA’s reported financial benefits to companies include lower customer turnover, fewer failures, and a reduction in employee hours allocated to resolving customer problems.

Management, Implementation, and Continuous Improvement

Near-misses provide insight into (a) potential failure points within the system being analyzed and (b) weaknesses in the management system itself. As such new incidents, whether near-misses or accidents, can provide an opportunity to address and remedy potential weaknesses. This is particularly the case when new incidents appear to be “repeats” of previous events, for this indicates that one of the eight

stages may have failed to ensure hazards exposed by the previous incident were fully remedied. Hall [33] presents an example in arguing that similar to the Space Shuttle Challenger incident, the Space Shuttle Columbia disintegration in 2003 also displayed characteristics of organizational failure, even though significant improvements had been made since the previous incident. Similarly, Hallstrom and Smith [34] noted that hurricane ANDREW was a near-miss for hurricane RITA.

Although it is highly desirable to implement an eight-step NMMS, various conflicts can arise between management and those involved with reporting when selecting an NMMS that implements one or more of these eight steps. In this regard, Meel *et al.* [35] modeled the conflicts and trade-offs of management and engineering preferences as compared with process operator preferences using game theory (*see Risk Measures and Economic Capital for (Re)insurers; Mathematics of Risk and Reliability: A Select History; Group Decision*) to demonstrate the complexity of selecting an NMMS to be implemented in a chemical plant. Given various favorable and unfavorable views, the benefit of selecting an NMMS that satisfies the preferences of both is emphasized.

The auditing of an NMMS could provide significant insights into the benefits and weaknesses of the eight-step process. For example, Filippi *et al.* [36] carried out an in-depth analysis of near-misses in obstetrical emergencies among 12 hospitals in Benin, Cote d’Ivoire, Ghana, and Morocco by conducting near-miss audits. Steps of an audit process included (a) identification of near-miss cases, (b) selection of case(s) for audit, (c) interview(s) with the women involved, (d) interviews of persons involved in the management of case(s), (e) preparation of a medical summary for each case, (f) assessment of the quality of care provided, and (g) follow-up recommendations for improvement. These audits resulted in a wide range of positive changes in the procedures and resources available for the management of obstetric complications.

Quantitative Analysis of Near-Misses

In the future, as the benefits of NMMS are realized, large amounts of near-miss data sets are likely to be available. However, for now, many disciplines have not yet reached that level of data availability. The lack of near-miss data in industries could be due to

either the lack of efforts by management and safety personnel in collecting near-misses or the lack of availability of such data in the discipline of interest. For example, the health care industry has significantly more data than the process industries, which, in turn, have more data than natural disaster agencies.

The collection of data and their analysis are critical to improve system reliability and should, therefore, be encouraged. In their study, Rosenthal *et al.* [37] discuss the potential role of a facility's process safety management system (PSMS) in preventing low-probability, high-consequence (LP-HC) events. They note that a lack of process incident/accident data hinders predicting the characteristics of a facility's PSMS that can help in reducing "low-probability, high-consequence" accidents.

Having a rich database can help identify key issues. Kwon *et al.* [38] analyzed 5500 near-miss cases of a Korean chemical plant using KOSHA Accident Causation Management System (KACMS) and found that removal of human errors is the key issue that is necessary to prevent these near-miss cases and improve the process reliability.

Data on accident precursors are used to estimate the failure probabilities of the safety systems. Kaplan [39] introduced the concept of precursors and near-misses in quantitative risk assessment of space shuttles using Bayesian theory (*see Insurance Pricing/Nonlife; Imprecise Reliability; Lifetime Models and Risk Assessment*). Yi and Bier [40] developed a systematic approach using copula to extract maximum information from near-misses at a nuclear plant.

The complex and nonlinear interactions in chemical plants lead to occurrence of near-misses with varying consequences, some leading to accidents. This necessitated process engineers to seek robust and improved risk assessment tools to improve reliability. In search of more comprehensive accident prediction power, Meel and Seider [41] introduced an extended classification approach for abnormal events in chemical industries based on the safety pyramid in Figure 1. For systematic calculations with improved understanding of event propagation, they classified abnormal events into four categories in increasing order of severity of their consequences: (a) incipient faults, (b) near-misses, (c) incidents, and (d) accidents, and assumed that in a typical accident scenario abnormal events propagate in the above order. They used Bayesian theory to conduct statistical analysis of abnormal events (a) to improve system reliability and

(b) to perform dynamic risk assessment of continuous processes. More specifically, they developed the following tools to be implemented as part of an effective NMMS [41]:

1. Forecasting analyzer

Predicts the rate of occurrence of events in a time interval.

2. Reliability analyzer

Predicts human and equipment reliability by estimating the failure probabilities of human actions and equipment associated. Furthermore, performance of safety systems, which are crucial in preventing accidents, is assessed under abnormal events to identify the systems where reliability is lacking.

3. Accident closeness analyzer

Estimates the proximity of plant state with time to near-misses incidents and accidents using fuzzy clustering (*see Reliability Optimization*).

Summary

NMMSs can be a powerful tool to reduce the risk and improve the reliability of an organization, or a production, or a service process. Having a broad definition, but specific to the application environment, is important to achieve the best results from an NMMS. Other essential features of an effective NMMS include (a) encouraging the reporting of as many near-misses as possible (a guideline of 1 near-miss per person per year is often suggested), (b) management owning the program and utilizing the information to improve the system reliability, and (c) using both individual incident information and statistical analysis of collective data to improve system performance. As in other safety and risk areas, the central factor is the participation of all affected parties in the management of risk. This is perhaps the most important feature of an effective NMMS.

ULKU OKTEM AND ANJANA MEEL

No Fault Found

The No Fault Found (NFF) phenomenon occurs in systems where a system is tested after a failure is reported but no failure is found during the test.

The inability to isolate a system fault during a test may occur for a number of reasons that may be related to the state of the system itself, and the state of, and the methods of operation of, the test equipment. In trying to understand NFF all three areas have to be considered.

Systems are generally considered to be complex items that may contain people, hardware, and software and often contain subsystems. These subsystems may also contain a hierarchy of low-level subsystems until a basic component level is reached. At each system level there may well be a combination of components and lower level subsystems. In most cases the human interface and also the presence of a person interacting with the system are considered as part of the system. At each of these discrete levels and for each item in the system, a NFF situation may occur. These situations often occur across level boundaries where, for instance, a failure is detected at the top level – perhaps by built-in test (BIT) – which also identifies a faulty subsystem (*see Failure Modes and Effects Analysis; Reliability Integrated Engineering Using Physics of Failure*). This causes a repair to be performed, which swaps the identified subsystem for another one and the top-level system then works perfectly. When the removed subsystem (often called a *line replaceable unit, LRU or line replaceable item, LRI*) is tested, however, no fault is found. This is the classic NFF case.

Nomenclature

This basic phenomenon is known by a large number of terms, which are often abbreviated to three letter acronyms. The following names and acronyms are encountered in different industries and in the existing literature: No Fault Found (NFF), No Failure Found (NFF), No Trouble Found (NTF), Re-Test OK (RTOK), Trouble Not Identified (TNI), Cannot Duplicate (CND), No Fault Indicated (NFI), No Defect Found (NDF), No Problem Found (NPF), Bad Actor

(BA), Fault Not Found (FNF), Failure Not Found (FNF), False Alarm (FA), Cause Not Found (CNF), and similar acronyms [1–7]. In this article the term *NFF* will be used throughout.

Industrial Occurrence of NFF

A large number of organizations and companies have reported anecdotally that the level of NFF found in their systems is around 50% of removed items and this means that occurrence of NFF is a large problem for industry. Because of this high incidence, a number of formal studies have been performed that have attempted to quantify the extent of the problem. The aerospace industry has reported average figures as around 50% [1, 8–12] and in at least two specific cases 67% [5] and 85% [4]. The portable phone market, however, seems to suffer similar levels of NFF; Reference [13] states that *One in seven mobile phones are returned within the first year of purchase by subscribers as faulty. Further analysis into the nature of these returns reveals the even more disturbing statistic that 63% of the devices being returned are without fault*. Reference [14] states that this figure is 13% over the industry average for general consumer electronic devices, which makes this average the typical 50%. The train industry has also reported occurrence levels of around 50% [15] whereas one automotive manufacturer has reported NFFs as high as 80–90% with a particular device [2]. More generic, cross-sector work [16] reported figures from 0 to 53%, with an average – where there was at least one incidence of NFF – of around 45%. Other authors [17] have also reported averages between 25 and 50%, and one author [18] reports the averages to be as high as 80%.

Costs of NFF

Each time a system is repaired the same repair cost is encountered whether or not the repair is effective and the reported percentage suggests that up to 90% of the maintenance cost could be used up in dealing with NFF [4]. An actual estimate of the loss of money globally in the portable phone markets is given in [14] as \$4.5 billion in 2006. In the aerospace industry the F-16 program spent over \$10 million on NFF diagnostics in 2001 [5], and the air transport association reported that NFFs cost

member airlines at least \$100 million dollars per year, not including costs derived from network disruptions. In the automotive industry, because a reputation for intermittent faults can be so damaging to a company, often product recalls are performed to attempt to fix these sort of issues, and one manufacturer reported that the recall of over a million vehicles in 1987 for such an issue had cost them many millions of dollars [2].

Other effects of NFF

Quantitative measures of reliability (e.g., mean time between failures for systems (*see Design of Reliability Tests; Reliability Growth Testing*), mean time between removals) and availability (e.g., maintenance-free operating period) will be affected by the incidence of NFF, providing more pessimistic estimates that will bias analysis of the performance of operational systems and provide very conservative estimates as inputs to quantitative risk modeling.

Refitting a subsystem that potentially has an undiagnosed failure to a system may increase risks with implications for safety [4]. To avoid this issue, Thomas *et al.* [2] suggest that a company takes full responsibility for finding the root cause of all failures. This partly falls in line with the work reported by James *et al.* [9], which has developed guidance for the aerospace industry for dealing with NFF.

Possible Causes of NFF

It has been often suggested anecdotally that the NFFs in electronic and mechanical systems are caused by the volume of complex components present in a system. Complex components would include hybrid devices, microprocessors, large memories, and ICs that contain a large number of operational units. Often these devices will contain untested regions, which may contain faults and could be utilized during operation in special circumstances. Replication of the exact failure circumstances may not be possible during failure analysis due to time and cost constraints. The more complex a printed circuit board, the less likely it is that a diagnostic will be successful even if the components are in themselves quite simple [1, 2, 8, 9, 19–22]. This is particularly true in the aerospace and

other industries for complex control circuitry particularly where software forms an integral part of the system. However, the work done in [16] seems to indicate that this is not the case.

Another anecdotal reason proposed for the incidence of NFF is the presence of connectors on the circuit boards [9, 16]. Connectors can corrode and cause intermittent failures owing to increase in contact resistance caused by corrosion products. Often the removal of the board from the equipment, and later insertion of the board into test apparatus, may clean the connector contacts causing the board to function correctly again. Service engineers will often clean connector contacts as a routine before testing the boards and hence repair the intermittent fault. Again, the work done in [16] seems to indicate that this is not the case.

For the system that is not electronic, there has been no reported work to date investigating the potential causes of NFF although it is expected that these will have similar root causes, overly complex base units and the interface between such units.

A further possible cause of NFF in all cases is as a result of human interaction with the system [16]. It is possible that during the use of a new system, the operator's expectations of how the system should operate could possibly be different from the system's actual operating parameters. This could lead to the reporting of failures when no failure is in fact present. The examination of the data reported in [14] allows some investigation of these issues where it was found that, for returned failed units, 38% were from users abandoning devices after struggling to use them, 13% were from users who claimed that the device did not fulfill the purpose for which it had been purchased, and 49% were from users who diagnosed lack of service preconfiguration as a device fault.

Management of NFF

There are two reasons why a subsystem is classified as No Fault Found. Either there is no fault in the product or the system test fails to detect the fault. Where there is really no fault present in the subsystem, it is not surprising that the test fails to locate one; however, what is more surprising is the fact that the subsystem was rejected in the first instance. Where there is a fault present in the product

but the test fails to isolate the defect, it is likely that this subsystem will exhibit the same behavior when reinstalled on a system. In the latter case, it will be the effectiveness of the operator's recording and reporting systems that will determine whether the subsequent subsystem rejections can influence the level of diagnostic activity carried out during the test. If a particular subsystem is removed on a number of occasions for the same symptom, it is likely to be the cause of the failure. Rapid classification and good visibility of repeat removals or rogue units can provide an operator with important information. Besides providing an indication that the particular subsystem is actually faulty, it also highlights the ineffectiveness of the system test in this particular area.

There is a third reason why a subsystem may be classified as No Fault Found in testing (although it is actually a subset of those events with "no fault present"). Subsystems will be removed during scheduled maintenance. A scheduled removal will be tested to ensure that there are no subsidiary faults present. Subsystems that pass a test following a scheduled removal and any upgrade have been sometimes classified as NFF along with those subsystems removed during unscheduled maintenance.

Where there is really no failure contained within the subsystem, then the reason for its rejection must be reviewed in detail if the root cause of the system malfunction is to be located. Although most workshop facilities will carry out an extensive test regimen without the benefit of environmental stressing, it is understandable that if a product contains an intermittent fault, it has a lower likelihood of being detected during test. If the workshop operatives are not familiar with the idiosyncrasies of each product's test regimen, then the interpretation of results may play a major part in the success of the workshop. To effectively reduce NFF removals, a subsystem supplier must have direct dialogue with relevant workshop staff to elicit the factors that may influence workshop effectiveness and then drive for methods to improve the situation for future products.

It is important to acknowledge that any complex system will, in its early life, contain uncovered design faults. As experience with a new system grows, similarities in the symptoms of NFF removal events will begin to develop. Failures may also begin to manifest themselves where a particular operator uses

the system in an area of its envelope not previously used by other operators.

In order to confirm that the defect isolated/repared within the subsystem is indeed the root cause of the system malfunction, a number of options are possible. Correlation of the subsystem failure with the maintenance message or reported anomalous behavior is the most commonly used. If a mechanism cannot be postulated to link the specific subsystem failure to the system behavior, then it may be that the subsystem simply contains a subsidiary fault, with the root cause still on the system. For this reason it is extremely important that a structured technique is used to confirm if the subsystem rejection was responsible for the system malfunction, particularly where it affects safety. If the system malfunction disappears following the replacement of a subsystem, it is likely that this will be the cause of the problem. However, this is not always the case and extreme caution should be given to the assumption that a subsystem is faulty because its replacement cured the problem.

In order to be confident that the reason for rejection is confirmed in the workshop, there must be good correlation between the system defect definition and the fault detected within the subsystem. This correlation should include test failure(s) within the workshop, an Failure Mode and Effect Analysis FMEA-type analysis to give potential system behavior for given subsystem faults, and the clearance of the fault upon the subsystem rejection.

JEFFREY A. JONES

Non- and Semiparametric Models and Inference for Reliability Systems

Components and Systems

The assessment of the risk of failure and the quality of deployed systems is of great importance in many settings, such as in the engineering, biomedical, public health, military, economic, and business arenas. It is therefore imperative to have probabilistic models and statistical inference methods for assessing the risk and quality of systems. Most of these systems can be conceptually modeled as reliability systems.

A reliability system (see **Multistate Systems**) is composed of a finite number of components, with such components possibly subsystems themselves. Such a system could be a mechanical, an electronic, a military, a biomedical, an economic, or even a managerial decision-making system. Such systems usually exist for the purpose of performing certain specific tasks. For a reliability system with K components, denote by $\mathbf{x} = (x_1, x_2, \dots, x_K)$ the state vector of the components, with $x_i \in \{0, 1\}$, and such that $x_i = 1$ if and only if component i is functioning. The structure function of a reliability system is the function $\phi: \{0, 1\}^n \rightarrow \{0, 1\}$ such that $\phi(\mathbf{x})$ indicates whether the system is in a functioning state ($\phi(\mathbf{x}) = 1$) or is in a failed state ($\phi(\mathbf{x}) = 0$). If the structure function ϕ satisfies the conditions that (a) it is nondecreasing in each argument, and (b) each component is relevant in the sense that, for each $i \in \{1, 2, \dots, K\}$, there exists an $\mathbf{x} \in \{0, 1\}^n$ such that $0 = \phi((0_i, \mathbf{x})) < \phi((1_i, \mathbf{x})) = 1$, where $(0_i, \mathbf{x}) = (x_1, \dots, x_{i-1}, 0, x_{i+1}, \dots, x_K)$ and $(1_i, \mathbf{x}) = (x_1, \dots, x_{i-1}, 1, x_{i+1}, \dots, x_K)$, then the reliability system is said to be a coherent system (see **Reliability Optimization**). We refer the reader to the excellent monograph of Barlow and Proschan [1] for a comprehensive treatment of coherent reliability systems.

Two common examples of coherent reliability systems are the series system whose structure function is $\phi_{\text{ser}}(\mathbf{x}) = \min(x_1, x_2, \dots, x_K)$ and the parallel system whose structure function is $\phi_{\text{par}}(\mathbf{x}) =$

$\max(x_1, x_2, \dots, x_K)$ (see **Game Theoretic Methods**). A more general coherent structure function is the k -out-of- K system whose structure function is $\phi_{k:K}(\mathbf{x}) = I\{\sum_{j=1}^K x_j \geq k\}$ with $I(A) = 0$ or 1 depending on whether event A does not or does hold, respectively. Thus, a k -out-of- K system is functioning if and only if at least k of its K components are functioning. Clearly, a series system is a K -out-of- K system, whereas a parallel system is a 1 -out-of- K system. Another coherent system, which is used to illustrate the procedures described in the sequel, is the series-parallel system whose structure function is $\phi_{\text{sp}}(x_1, x_2, x_3) = \min\{x_1, \max\{x_2, x_3\}\}$. This system functions so long as component 1 and at least one of components 2 and 3 are functioning.

Denote by X_i the random variable indicating whether component i is in a functioning state, and let $p_i = \Pr\{X_i = 1\}$, $i = 1, 2, \dots, K$. Assume that $X_1, X_2, \dots, X_K$ are independent random variables, and define $\mathbf{X} = (X_1, X_2, \dots, X_K)$ and $\mathbf{p} = (p_1, p_2, \dots, p_K)$. The reliability function associated with the structure function ϕ is defined by

$$h_\phi(\mathbf{p}) = E\{\phi(\mathbf{X})\} = \Pr\{\phi(\mathbf{X}) = 1\} \quad (1)$$

This reliability function represents the probability that the system is functioning. The series system has the reliability function $h_{\text{ser}}(\mathbf{p}) = \prod_{j=1}^K p_j$, while the reliability function of the parallel system is $h_{\text{par}}(\mathbf{p}) = 1 - \prod_{j=1}^K (1 - p_j)$. For the more general k -out-of- K system, the reliability function is

$$h_{k:K}(\mathbf{p}) = \sum_{\{(x_1, x_2, \dots, x_K) \in \{0, 1\}^K; \sum_{j=1}^K x_j \geq k\}} \prod_{j=1}^K p_j^{x_j} \quad (2)$$

In the special case where $p_j = p$, $j = 1, 2, \dots, K$, this reliability function simplifies to $h_{k:K}(p) = \sum_{j=k}^K C(K, j) p^j (1 - p)^{K-j}$, where $C(K, j)$ is the combination of K items taken j at a time. Thus, in this case, $h_{\text{ser}}(p) = h_{K:K}(p) = p^K$ and $h_{\text{par}}(p) = h_{1:K}(p) = 1 - (1 - p)^K$. On the other hand, for the series-parallel system, the reliability function is $h_{\text{sp}}(p_1, p_2, p_3) = p_1[1 - (1 - p_2)(1 - p_3)]$, which simplifies to $h_{\text{sp}}(p) = p(1 - (1 - p)^2)$ when all three components have the same reliability p .

The structure function and the reliability function are characteristics of the reliability system at a specific point in time. Because it is usually of interest to determine if the system will be able to accomplish

a specific task within a given period of time, it is fruitful to consider the evolution of the system as time moves forward. This entails the examination of the component and system lifetimes (*see Reliability Data; Extreme Values in Reliability*).

Nonparametric Models

Denote by $\mathbf{T} = (T_1, T_2, \dots, T_K)$ the vector of component lifetimes and by S the system lifetime. For a given time t , the state vector of the components is given by

$$\mathbf{X}(t) = (I(T_1 > t), I(T_2 > t), \dots, I(T_K > t)) \quad (3)$$

hence the state of the system at time t is given by $\phi(\mathbf{X}(t))$. Consequently, $\{S > t\} = \{\phi(\mathbf{X}(t)) = 1\}$. The system lifetime survivor function is therefore

$$\bar{F}_\phi(t) = \Pr\{S > t\} = \Pr\{\phi(\mathbf{X}(t)) = 1\} = E\{\phi(\mathbf{X}(t))\} \quad (4)$$

If the component lifetimes are independent and their survivor functions are given by $\bar{F}_j(t) = \Pr\{T_j > t\}$, $j = 1, 2, \dots, K$, then the system survivor function could be expressed in terms of the system's reliability function *via*

$$\bar{F}_\phi(t) = h_\phi(\bar{F}_1(t), \bar{F}_2(t), \dots, \bar{F}_K(t)) \quad (5)$$

A special case, for instance, is when the component lifetimes are independent exponentially distributed random variables with the j th component having mean lifetime of $1/\lambda_j$. Then $\bar{F}_j(t) = I(t < 0) + \exp(-\lambda_j t)I(t \geq 0)$, hence the system lifetimes for the series and parallel systems have survivor functions given by, for $t \geq 0$,

$$\bar{F}_{\text{ser}}(t) = \exp \left\{ - \left(\sum_{j=1}^K \lambda_j \right) t \right\}$$

and
$$\bar{F}_{\text{par}}(t) = 1 - \prod_{j=1}^K [1 - \exp(-\lambda_j t)] \quad (6)$$

For the series-parallel system, the survivor function under the exponentially distributed component lifetimes becomes

$$\bar{F}_{\text{sp}}(t) = \exp\{-\lambda_1 t\} \{1 - [1 - \exp(-\lambda_2 t)] \times [1 - \exp(-\lambda_3 t)]\} \quad (7)$$

Other possible parametric distributional models for the component lifetimes are the Weibull family,

the gamma family, the lognormal family, and other classes of distributions for positive-valued random variables. Given a specification of the component lifetime distributions, a system lifetime distribution is induced. For example, with exponential component lifetimes, an exponential system lifetime distribution under a series system and a nonexponential system lifetime distribution under a parallel system arise.

In the engineering, reliability, and military settings, in contrast to biomedical and public health settings, it may be reasonable to assume a parametric model for the distributions of the component lifetimes, and consequently, the system lifetime distribution. However, if the assumed parametric forms are misspecified, then erroneous inference and decisions may ensue. Robust inference procedures are therefore obtained by not imposing potentially restrictive parametric forms for the distributions, but rather simply by assuming that the F_j 's belong to the class of continuous distributions, or to some more specific nonparametric class of lifetime distributions such as the class of increasing failure rate on average (IFRA) distributions (*cf.*, Barlow and Proschan [1] for discussions on such classes of lifetime distributions) (*see Imprecise Reliability*). In the next section, we examine methods of inference under this nonparametric setting.

Nonparametric Inference

Let us consider the situation in which n identical systems are followed over some observation window. We suppose that the i th system is monitored until time τ_i , where the τ_i could be an administrative time, or it could be time to failure due to other causes not related to component failures (e.g., an accident). Denote the system lifetimes by $S_1, S_2, \dots, S_n$. However, because monitoring of the i th system is terminated at time τ_i , if the system is still functioning at time τ_i , then we will only know that the system lifetime exceeded τ_i . The observables for the n systems will therefore be

$$(\mathbf{Z}, \delta) = ((Z_1, \delta_1), (Z_2, \delta_2), \dots, (Z_n, \delta_n)) \quad (8)$$

where $Z_i = \min(S_i, \tau_i)$ and $\delta_i = I\{S_i \leq \tau_i\}$. The observable vector $(\mathbf{Z}, \delta)$ is referred to as the right-censored data for the n systems (*see Competing Risks*). It is of interest to make inferences about the system lifetime survivor function $\bar{F}_\phi(\cdot)$ based on $(\mathbf{Z}, \delta)$.

A nonparametric estimator of $\bar{F}_\phi$ is the product-limit estimator (PLE), also called the *Kaplan–Meier estimator* (see **Detection Limits**) in honor of its developers (*cf.*, Kaplan and Meier [2]). To describe this estimator in a compact form, we introduce some stochastic processes. Define the processes $N = \{N(s) : s \geq 0\}$ and $Y = \{Y(s) : s \geq 0\}$ according to

$$N(s) = \sum_{i=1}^n I\{Z_i \leq s, \delta_i = 1\}$$

and $Y(s) = \sum_{i=1}^n I\{Z_i \geq s\}$ (9)

The PLE of $\bar{F}_\phi$ is given by

$$\hat{\bar{F}}_\phi(t) = \prod_{s=0}^t \left[1 - \frac{dN(s)}{Y(s)} \right] \quad (10)$$

In the event that there are no right-censored observations, so $\delta_i = 1, i = 1, 2, \dots, n$, the PLE reduces to

$$\hat{\bar{F}}_\phi(t) = \frac{1}{n} \sum_{i=1}^n I\{S_i > t\} \quad (11)$$

the empirical survivor function. If the τ_i 's have a common distribution function $G(t) = \Pr\{\tau_1 \leq t\}$, it is well known from Efron [3] and Breslow and Crowley [4] that when the τ_i 's are independent of the T_{ij} s and n is large, $\hat{\bar{F}}_\phi(t)$ is approximately normally distributed with mean $\bar{F}_\phi(t)$ and asymptotic variance given by

$$\text{Var}\{\hat{\bar{F}}_\phi(t)\} = \frac{1}{n} [\bar{F}_\phi(t)]^2 \int_0^t \frac{-d\bar{F}_\phi(u)}{\bar{F}_\phi(u)^2 \bar{G}(u-)} \quad (12)$$

The PLE presented above is entirely based on the right-censored system lifetimes. A more efficient estimator of $\bar{F}_\phi(t)$ may be obtained provided that the failure times of the components that failed can be determined, and by exploiting the relationship between the system's reliability function and the system lifetime in equation (5). The idea is to obtain individual estimates of the $\bar{F}_j$, $j = 1, 2, \dots, K$, based on the j th component's right-censored data, and to plug these estimates in the system's reliability function to obtain an estimate of the system survivor function. This approach was implemented in Doss *et al.* [5]. We describe this more efficient estimator below.

For the i th system, denote by T_{ij} the lifetime of component j . Define $Z_{ij} = \min\{T_{ij}, S_i, \tau_i\}$ and $\delta_{ij} = I\{T_{ij} \leq \min(S_i^*, \tau_i)\}$. The right-censoring variable

for T_{ij} involves S_{ij}^* , which is the system lifetime of the original system but with the j th component perpetually functioning, so that the distribution of the resulting censoring variable is dependent on the structure function ϕ . More specifically, S_{ij}^* has survivor function given by

$$\bar{F}_j^*(t) = \Pr\{S_{ij}^* > t\} = h_\phi(\bar{F}_1(t), \dots, \bar{F}_{j-1}(t), 1, \dots, \bar{F}_{j+1}(t), \dots, \bar{F}_K(t)) \quad (13)$$

Next, for $i = 1, 2, \dots, n$ and $j = 1, 2, \dots, K$, define the stochastic processes

$$N_{ij}(s) = I\{Z_{ij} \leq s; \delta_{ij} = 1\}$$

$$\text{and } Y_{ij}(s) = I\{Z_{ij} \geq s\} \quad (14)$$

Aggregate these processes according to $N_j(s) = \sum_{i=1}^n N_{ij}(s)$ and $Y_j(s) = \sum_{i=1}^n Y_{ij}(s)$. The PLE of $\bar{F}_j(t)$ is then given by

$$\hat{\bar{F}}_j(t) = \prod_{s=0}^t \left[1 - \frac{dN_j(s)}{Y_j(s)} \right], \quad j = 1, 2, \dots, K \quad (15)$$

where $Z_{(n)j} = \max_{1 \leq i \leq n} Z_{ij}$. From PLE theory, if τ_i has survivor function $\bar{G}(t)$, then, for large n , $(\hat{\bar{F}}_1(t), \dots, \hat{\bar{F}}_K(t))$ will be approximately multivariate normal with mean $(\bar{F}_1(t), \dots, \bar{F}_K(t))$ and asymptotic covariance matrix of $\frac{1}{n} \Sigma_\phi(t)$ with

$$\Sigma_\phi(t) = \text{Dg} \left(\bar{F}_j(t)^2 \int_0^t \frac{-d\bar{F}_j(u)}{\bar{F}_j(u)^2 \bar{F}_j^*(u-)} \bar{G}(u-), \right. \\ \left. j = 1, 2, \dots, K \right) \quad (16)$$

where $\text{Dg}(\mathbf{a})$ denotes the diagonal matrix induced by $\mathbf{a}$.

From the component lifetime survivor function estimators in equation (15) and by equation (5), we form the component-based PLE of $\bar{F}_\phi(t)$ via

$$\tilde{\bar{F}}_\phi(t) = h_\phi(\hat{\bar{F}}_1(t), \hat{\bar{F}}_2(t), \dots, \hat{\bar{F}}_K(t)) \\ \times I\left\{t \leq \max_{i,j} Z_{ij}\right\} \quad (17)$$

Let

$$\mathbf{A}_\phi(p_1, \dots, p_K) = \left(\frac{\partial h_\phi(\mathbf{p})}{\partial p_j}, j = 1, 2, \dots, K \right) \quad (18)$$

which is the vector consisting of the reliability importance of the components. By the δ method, for

large n , it follows that $\tilde{\tilde{F}}_\phi(t)$ will be approximately normal with mean $\bar{F}_\phi(t)$ and asymptotic variance of

$$\text{Var}\left\{\tilde{\tilde{F}}_\phi(t)\right\} = \frac{1}{n} \mathbf{A}_\phi(\bar{F}_1(t), \dots, \bar{F}_K(t)) \Sigma_\phi(t) \mathbf{A}_\phi(\bar{F}_1(t), \dots, \bar{F}_K(t))' \quad (19)$$

As shown in Doss *et al.* [5], the estimator in equation (17) of the system lifetime survivor function is more efficient, in the sense of smaller variance, than the ordinary PLE $\hat{\tilde{F}}_\phi(t)$ given in equation (10). On the other hand, it should be recognized that $\tilde{\tilde{F}}_\phi(t)$ is a more complicated estimator than $\hat{\tilde{F}}_\phi(t)$. Furthermore, to construct $\tilde{\tilde{F}}_\phi(t)$, the exact failure times of the components that failed need to be known, which may not be feasible in practice, whereas the estimator $\hat{\tilde{F}}_\phi(t)$ only requires the right-censored system lifetimes.

Having obtained estimators of the system life survivor function in the form of $\hat{\tilde{F}}_\phi$ or $\tilde{\tilde{F}}_\phi$, one could use them to obtain estimators of other relevant parameters of the system lifetime, such as the mean, standard deviation, median, or quantiles. For instance,

possible estimators of the mean system lifetime are

$$\begin{aligned} \hat{\mu}_\phi &= - \int_0^\infty t d\hat{\tilde{F}}_\phi(t) \\ \text{and } \tilde{\mu}_\phi &= - \int_0^\infty t d\tilde{\tilde{F}}_\phi(t) \end{aligned} \quad (20)$$

Observe that since both $\hat{\tilde{F}}_\phi$ and $\tilde{\tilde{F}}_\phi$ are step functions the above integrals are just finite sums.

We illustrate these concepts with an example, using the three-component series-parallel system. For each of the three components we generate 20 random variates from the exponential distribution with mean 1. System survival times and the failure indicator random variables, $(\mathbf{Z}, \delta)$, are generated using this information and the structure function $\phi_{sp}(x_1, x_2, x_3) = \min\{x_1, \max\{x_2, x_3\}\}$. We also allow for random censoring *via* an exponential distribution with mean 1. Table 1 shows the raw data for the system times and the hand calculations for the PLE of $\tilde{F}_{sp}$, denoted by $\hat{\tilde{F}}_{sp}$. We repeat these calculations for each of the three components in the series-parallel system by using the ordered pairs $(\mathbf{Z}_j, \delta_j)$, $j = 1, 2, 3$. We show the raw data for the component times and the PLEs

Table 1 The system lifetimes and failure indicator are shown in the first two columns. Jumps in the $N(\cdot)$ counting process and changes in the at-risk counter, $Y(\cdot)$, are also given. Calculations for the PLE based on system lifetimes, $\hat{\tilde{F}}_{sp}$, are displayed

$Z_{(i)}$	$\delta_{(i)}$	$\Delta N(Z_{(i)})$	$Y(Z_{(i)})$	$\frac{\Delta N(Z_{(i)})}{Y(Z_{(i)})}$	$1 - \frac{\Delta N(Z_{(i)})}{Y(Z_{(i)})}$	$\hat{\tilde{F}}_{sp}(Z_{(i)})$

for $\bar{F}_j$ for each of the components in Table 2. We then obtain the component-based PLE of $\bar{F}_{sp}$, denoted by $\hat{\bar{F}}_{sp}$, by evaluating the reliability function, $h_{sp}(p_1, p_2, p_3) = p_1[1 - (1 - p_2)(1 - p_3)]$ at $p_j = \hat{\bar{F}}_j(t)$, for $j = 1, 2, 3$ and $t \leq \max_{i,j} Z_{ij}$. Otherwise, we define $\hat{\bar{F}}(t) = 0$ when $t > \max_{i,j} Z_{ij}$. Note that statistical software, such as R, have built-in functions for calculating the PLE of $\bar{F}_{sp}$ and $\bar{F}_j$, for $j = 1, 2, 3$. The component-based PLE of $\bar{F}_{sp}$ is also shown in Table 2.

When the failure times for each of the components in the series–parallel system follows an exponential distribution with mean 1, the true system survivor function is given by

$$\bar{F}_{sp}(t) = \exp(-t)\{1 - [1 - \exp(-t)]^2\} \quad (21)$$

The PLE of $\bar{F}_{sp}$, the component-based PLE of $\bar{F}_{sp}$, and the true survivor function are shown in Figure 1.

The component-based PLE mimics the behavior of the system-based PLE closely. Both are comparable to the true survivor function.

Semiparametric Models

The models and inference methods considered in the preceding sections are restrictive, since they do not take into account the impact of covariates such as environmental conditions, operating characteristics, demographic variables, etc. This is especially crucial in the assessment of the risk or quality of systems, since the incorporation of relevant covariates may lead to more precise and accurate knowledge. In this section, we discuss models that incorporate covariates, and provide some inference methods for these models.

Consider a system whose performance is affected by a vector of covariates, say, a $q \times 1$ vector

Figure 1 The PLE of $\bar{F}_{sp}$ denoted by $\hat{\bar{F}}_{sp}$ (solid line) and the component-based PLE of $\bar{F}_{sp}$ denoted by $\tilde{\bar{F}}_{sp}$ (dashed line) are shown using 20 randomly generated component and system failure times for the series-parallel system. The true survivor function is also shown (dotted line)

$\mathbf{V} = (V_1, V_2, \dots, V_q)'$. Such a covariate vector could be time-dependent; however, for simplicity we restrict ourselves to time-independent covariates. The simplest type of model directly relates the system lifetime S to the covariate vector $\mathbf{V}$. The two major models for doing so are accelerated failure time (AFT) models (also referred to as *log-linear models*) and hazard-based models.

In the AFT model, one postulates that

$$\log(S) = \beta\mathbf{V} + \sigma\epsilon \quad (22)$$

where $\beta = (\beta_1, \beta_2, \dots, \beta_q)$ is a $1 \times q$ vector of regression coefficients, σ is a dispersion parameter, and ϵ is an error component whose distribution is typically assumed to belong to some parametric family of distributions. The appealing trait of these AFT models is the easy interpretability of the regression coefficients. Technically, however, this AFT model is still a parametric model, in contrast to the next class of models, which are semiparametric.

To introduce hazard-based models, we recall relevant functions. For a continuous positive random variable T , with density function $f(t)$ and survivor function $\bar{F}(t)$, the hazard rate function and the hazard function are defined, respectively, via

$$\lambda(t) = \frac{f(t)}{\bar{F}(t)} \quad \text{and} \quad \Lambda(t) = \int_0^t \lambda(u) du \quad (23)$$

These functions are related to f and $\bar{F}$ according to $f(t) = \lambda(t) \exp\{-\Lambda(t)\}$ and $\bar{F}(t) = \exp\{-\Lambda(t)\}$. The intuitive interpretation of $\lambda(t)(\Delta t)$, where Δt is a small positive number, is that this is the approximate conditional probability that $T \leq t + \Delta t$, given that $T \geq t$, that is, the probability of failing in a small interval starting from t given that the unit is alive just after t .

The Cox proportional hazards (PH) model (cf., Cox [6]) (see **Lifetime Models and Risk Assessment; Hazard and Hazard Ratio**) relates the system lifetime to the covariate vector $\mathbf{V}$ according to

$$\lambda_{s|\mathbf{V}}(s|\mathbf{v}) = \lambda_0(s) \exp\{\beta\mathbf{v}\} \quad (24)$$

where $\lambda_0(\cdot)$ is some baseline hazard rate function which is nonparametrically specified. This is a semiparametric model, since there is an infinite-dimensional parameter $\lambda_0(\cdot)$ and a finite-dimensional parameter β . It is well known (cf., Kalbfleisch and Prentice [7]) that the AFT model and the Cox PH model coincide if and only if the baseline hazard rate function $\lambda_0(t)$ belongs to the Weibull class, that is, $\lambda_0(t) = (\alpha\gamma)(\gamma t)^{\alpha-1}$. In this case, the distribution of the error term in the AFT model is the extreme-value distribution. Since the focus of this article is on nonparametric and semiparametric models, we henceforth concentrate on the Cox PH-type model. It should be noted that if $\bar{F}_0(t)$ is the survivor function associated with the baseline hazard rate function $\lambda_0(\cdot)$, then the conditional survivor function of the system lifetime under the Cox PH model, given $\mathbf{V} = \mathbf{v}$, is

$$\bar{F}_\phi(t|\mathbf{v}) = [\bar{F}_0(t)]^{\exp(\beta\mathbf{v})} \quad (25)$$

Perhaps, it may be difficult to justify the proportionality postulate for the system lifetime hazard function in the Cox model, since the system lifetime is determined by the component lifetimes and the structure function of the system. Instead, it may be easier to provide justification for such a proportionality assumption when dealing with the lifetimes at the component level. We could therefore have an alternative model wherein the Cox PH model is imposed at the component level. This will then induce a model for the system lifetime. However, the resulting system lifetime model need not anymore be of the Cox PH-type. This was the approach explored in Hollander and Peña [8]. To elaborate on this alternative model, for the j th ($j = 1, 2, \dots, K$) component lifetime T_j ,

we postulate that the conditional hazard rate function of T_j , given $\mathbf{V} = \mathbf{v}$, is

$$\lambda_j(t|\mathbf{v}) = \lambda_{0j}(t) \exp\{\beta_j \mathbf{v}\} \quad (26)$$

where $\lambda_{0j}(\cdot)$'s are baseline hazard rate functions, and β_j 's are $1 \times q$ regression coefficient vectors. This will entail that the conditional survivor function for the j th component is

$$\bar{F}_j(t|\mathbf{v}) = [\bar{F}_{0j}(t)]^{\exp\{\beta_j \mathbf{v}\}} \quad (27)$$

where $\bar{F}_{0j}$ is the survivor function associated with λ_{0j} . Consequently, the conditional survivor function for the system lifetime is given by

$$\bar{F}_\phi(t|\mathbf{v}) = h_\phi(\bar{F}_1(t|\mathbf{v}), \bar{F}_2(t|\mathbf{v}), \dots, \bar{F}_K(t|\mathbf{v})) \quad (28)$$

As a simple example, if the system is series, then the conditional system survivor function is $\bar{F}_{\text{ser}}(t|\mathbf{v}) = \prod_{j=1}^K [\bar{F}_{0j}(t)]^{\exp\{\beta_j \mathbf{v}\}}$, whose associated conditional hazard rate function is

$$\lambda_{\text{ser}}(t|\mathbf{v}) = \sum_{j=1}^K \lambda_{0j}(t) \exp\{\beta_j \mathbf{v}\} \quad (29)$$

which is not anymore of the Cox PH-type model, but rather is an additive Cox PH-type model. If one could assume, however, that $\beta_1 = \beta_2 = \dots = \beta_K = \beta$, then equation (29) reduces to a Cox PH-type model with a baseline hazard rate function of $\lambda_0(t) = \sum_{j=1}^K \lambda_{0j}(t)$.

Semiparametric Inference

Consider the situation in which n systems with the same structure function ϕ are monitored, and with the i th system associated with a covariate vector $\mathbf{v}_i$. As in an earlier section, the goal is to infer about the system lifetime survivor function and also the dependence of this survivor function on the covariates. We first consider the Cox-type model given in equation (24). We assume that system j is monitored over the period $[0, \tau_i]$, and so the observables are $\{(Z_i, \delta_i, \mathbf{v}_i), i = 1, 2, \dots, n\}$, where $Z_i = \min(S_i, \tau_i)$ and $\delta_i = I\{S_i \leq \tau_i\}$. On the basis of this data, the goal is to estimate both the baseline survivor function $\bar{F}_0(t)$ and the regression coefficient vector β , which will then lead to an estimate of the conditional system lifetime survivor function. Estimators of these parameters were obtained in Cox [6] and the properties of these

estimators were rigorously developed in Andersen and Gill [9]. We describe these estimators and some of their properties.

As developed by Cox in his seminal paper [6], when $\lambda_0(\cdot)$ is nonparametrically specified, the estimator of β is the maximizer of the so-called partial likelihood function. To describe this partial likelihood function in modern stochastic process notation, for $i = 1, 2, \dots, n$, define the processes

$$N_i(t) = I\{Z_i \leq t; \delta_i = 1\}$$

$$\text{and } Y_i(t) = I\{Z_i \geq t\} \quad (30)$$

The partial likelihood function is given by

$$L_P(\beta) = \prod_{i=1}^n \prod_{t=0}^{\infty} \left[\frac{\exp\{\beta \mathbf{v}_i\}}{\sum_{l=1}^n Y_l(t) \exp\{\beta \mathbf{v}_l\}} \right]^{dN_i(t)} \quad (31)$$

The $\hat{\beta}$ which maximizes this function is called the *partial likelihood maximum-likelihood estimator* (PLMLE) of β , and it could be obtained using iterative numerical methods. See, for instance, Fleming and Harrington [10], Andersen *et al.* [11], and Therneau and Grambsch [12] for procedures for computing $\hat{\beta}$. When n is large and under regularity conditions, it has been established in Andersen and Gill [9] that $\hat{\beta}$ is approximately normally distributed with mean β and a covariance matrix, which is approximated by

$$\widehat{\text{Cov}}(\hat{\beta}) = \left(-\frac{\partial^2 \log L_P(\beta)}{\partial \beta \partial \beta'} \Big|_{\beta=\hat{\beta}} \right)^{-1} \quad (32)$$

These results could be used to determine the importance of covariates by performing hypothesis tests and constructing confidence intervals for components of β .

To obtain an estimator of the baseline survivor function, we first get an estimator of the baseline hazard function Λ_0 . The estimator for this function, called the *Aalen–Breslow–Nelson estimator*, is given by

$$\hat{\Lambda}_0(t) = \sum_{i=1}^n \int_0^t \frac{dN_i(u)}{\sum_{l=1}^n Y_l(u) \exp\{\hat{\beta} \mathbf{v}_l\}}, \quad t \geq 0 \quad (33)$$

By virtue of the product–integral representation of a survivor function in terms of its hazard function

given by

$$\bar{F}_0(t) = \prod_{u=0}^t [1 - d\Lambda_0(u)] \quad (34)$$

a substitution-type estimator of $\bar{F}_0$ is obtained via

$$\hat{\bar{F}}_0(t) = \prod_{u=0}^t \left[1 - \frac{dN_i(u)}{\sum_{l=1}^n Y_l(u) \exp\{\hat{\beta}\mathbf{v}_l\}} \right] \quad (35)$$

Consistency properties and the joint asymptotic normality of $(\hat{\beta}, \hat{\Lambda}_0(\cdot))$, and consequently of $(\hat{\beta}, \hat{\bar{F}}_0(\cdot))$, were rigorously established in Andersen and Gill [9] using martingale methods.

Finally, an estimator of the conditional system survivor function is obtained through substitution to yield

$$\hat{\bar{F}}_\phi(t|\mathbf{v}) = \left[\hat{\bar{F}}_0(t) \right]^{\exp\{\hat{\beta}\mathbf{v}\}} \quad (36)$$

The importance of having such an estimator of $\bar{F}_\phi(t|\mathbf{v})$ is that one will be able to assess the probability of the system completing a task within a specified period of time for a given set of values of the covariates. This eventually could provide a more informed knowledge about the risk associated with employing the system and the level of quality of the system.

The estimator of the conditional system lifetime survivor function utilizes only the possibly right-censored system lifetimes. This is bound to be less efficient if the failure times of components that have failed can be determined, as in the case when there are no covariates. Analogously to the estimator $\hat{\bar{F}}_\phi(t)$ in equation (17) for the no-covariate case, we may exploit the relationship among the component conditional survivor functions $\bar{F}_j(t|\mathbf{v})$, $j = 1, 2, \dots, K$, and $\bar{F}_\phi(t|\mathbf{v})$ through the system reliability function as provided in equation (28). In particular, we suppose that the component failure times are related to the covariate vector according to a Cox PH model as specified in equation (26). By employing the analogous estimation procedures for $(\beta, \bar{F}_0)$ as described above, we can obtain the PLMLE and Aalen–Breslow–Nelson estimators, for each $j = 1, 2, \dots, K$, of $(\beta_j, \bar{F}_j(t|\mathbf{v}))$, denoted

by $(\hat{\beta}_j, \hat{\bar{F}}_j(t|\mathbf{v}))$. To obtain estimates for the j th component parameters, we use the observable data given by $\{(Z_{ij}, \delta_{ij}, \mathbf{v}_i), i = 1, 2, \dots, n\}$, where $Z_{ij} = \min(T_{ij}, S_i, \tau_i)$ and $\delta_{ij} = I\{T_{ij} \leq \min(S_{ij}^*, \tau_i)\}$, with S_{ij}^* as defined before. The estimator of the system conditional survivor function becomes

$$\begin{aligned} \hat{\bar{F}}_\phi(t|\mathbf{v}) &= h_\phi \left(\hat{\bar{F}}_1(t|\mathbf{v}), \hat{\bar{F}}_2(t|\mathbf{v}), \dots, \hat{\bar{F}}_K(t|\mathbf{v}) \right) \\ &\times I \left\{ t \leq \max_{i,j} Z_{ij} \right\} \end{aligned} \quad (37)$$

If the component failure times can be ascertained and the component Cox PH models hold, then this estimator is bound to be more efficient than the estimator $\hat{\bar{F}}_\phi(t|\mathbf{v})$. However, more research regarding the properties of the estimator in equation (37) is still warranted. Also, we point out that an efficiency comparison of the two estimators may not be entirely appropriate, since the Cox PH model for the system lifetime need not arise from the component Cox PH models which was the basis of the estimator in equation (37).

Dynamic Models

The probabilistic models considered in earlier sections are static in nature, in the sense that there is no proviso for the impact of the failed components on still functioning components. For instance, when components fail in a nonseries system, there might incur more load or stresses on the remaining functioning components to the extent that their residual failure rates may increase. Models that incorporate the evolving nature of coherent systems are referred to as dynamic models. Because of space limitations, we do not dwell on these models in this article, but simply restrict ourselves to alerting the reader to some recent pertinent work dealing with dynamic models. For instance, Hollander and Peña [13] discussed the need for such dynamic models when dealing with coherent structures and demonstrated the ensuing theoretical difficulties and complications arising from dynamic models. A general class of dynamic models for recurrent events, which is applicable to the modeling of coherent systems, was proposed in Peña and Hollander [14]. Some inference procedures for this class of models were described in the recent papers of Kvam and Peña [15], Peña *et al.* [16], and Stocker and Peña

[17]. Nevertheless, further research is called for to ascertain properties of dynamically modeled systems and to develop appropriate statistical inference procedures for such models.

Nonlife Insurance Markets

The Nature of Nonlife Insurance

Consumers and businesses prefer to avoid risk and uncertainty that have significant impact on their future income, wealth, or business prospects. They are in general risk averse, meaning they are willing to pay to avoid their individual risks. Risk pooling and the statistical law of large numbers make this possible and are the fundamentals of the insurance industry. By pooling a large number of risks where the causes of loss are significantly independent of each other, the insurance companies are able to predict the claims level to a reasonable degree of certainty. Pooling risks may be seen as portfolio diversification, where unsystematic random risks are reduced or eliminated by risk diversification and only systematic portfolio risks remain as the main risks to cover. Hence, insurance companies are better able to manage and absorb risks than individual consumers and businesses. In effect, consumers and businesses are transferring an uncertain payment in exchange for a much more certain payment, the insurance premium. Insurance exhibits economies of scale and it allows the economy as a whole to be more enterprising and to undertake longer term capital expenditure decisions which otherwise might not be made, or might be delayed. A well functioning nonlife insurance industry is one of the efficient fundamentals of local as well as global economies.

Market Characteristics

Regulations and Legislations

Market regulations and legislations controlled by federal legal authorities are crucial market constraints in nonlife insurance. The aim of the regulations is to protect both consumers and suppliers. Most commonly the directives relate to capital solvency, compulsory insurances, protection of consumers, and competition regulations, including pricing. In general we may differ between regulated and deregulated markets. The global trend is to deregulate to increase the market competition and hence stimulate better

and more efficient insurance solutions and customer service. The deregulation has particularly led to freedom in insurance pricing as a lever to increase competition. While premium tariffs have standard federal structures in highly regulated markets, price cooperation is not permitted between suppliers in fully price-deregulated markets.

Unlike the deregulation of competition and pricing, the global trend for consumer protection and insurance solvency is rather to strengthen the impact of these directives. The idea is to ensure efficient competition within society friendly and financially reliable market conditions. The solvency regulation in a nonlife insurance market is particularly important and affects the capital requirements of the insurance companies. Actuarial claims loss reserving is e.g., an important part of the solvency (*see Solvency*) regulatory. Strict solvency rules ensure the companies to have enough money to pay their future insurance liabilities and debts, and therefore protect both customers and shareholders.

The deregulation of nonlife insurance markets over the last two decades has increased mergers and acquisitions and thus the consolidation in most markets. The more cross-border regulatory harmonization takes place, the more cross-border consolidation and competition has appeared. Solvency objective, cost and revenue efficiency, and scale economy are major reasons behind mergers and acquisitions. A study by Cummins and Xie [1] concludes that acquiring firms in the US property-liability (P-L) industry achieve more revenue efficiency growth than nonacquirers, and that target firms experience greater cost and allocative efficiency than nontargets. Their main conclusions are that operating synergy exists between acquirers and target firms in the US P-L industry, and that the restructuring of the industry in the 1990s and early 2000s has produced efficiency gains.

Profitability and Underwriting Cycles

The profitability of the nonlife insurance industry has – like other industries – varied over time. However, the profitability has empirically tended to swing between profitable and unprofitable time periods alternating over time cycles. This observation is commonly known as the *underwriting* or *insurance* cycle and has traditionally been an important feature of nonlife insurance markets. Three explanations of the underwriting cycle have some degree of empirical

support; see [2]. These are cash flow underwriting, cost of equity and claims shock theory. *Cash flow underwriting* refers to a negative correlation between return on investments and insurance premium rates. *Cost of equity* refers to a downward pressure on insurance prices when stock markets rise above normal levels and hence generates an increase in insurance companies' available capital and a fall in their cost of capital. The *claims shock theory* states that insurance pricing tends to underestimate the potential for future claims during periods when there are no large individual claims or clusters of claims, while insurance prices rise sharply when such claims occur. This explanation is based on traditional economic shock model theories and assumes that the insurance market has a short memory.

Market Rivalry and Entry Dynamics

A market is a place where supply meets demand. In general, nonlife insurance markets are incomplete or inefficient, that is, there exist no markets with free entry and exit, nontransaction costs, perfect information, and pure rational customers. In effect, price is *not* the only competitive lever in incomplete markets when customers choose their insurers. Thus the insurers should take this incompleteness into account in their pricing models; see section titled "Pricing and Underwriting". Incomplete insurance market models have been widely studied within the theory of insurance economics. Competitive insurance market equilibria, optimal risk sharing and (Pareto) optimal insurance contracts, given incomplete market assumptions, are holistic quantitative model-based research areas which give valuable insights into the nature of insurance markets; see [3] for further reading.

The market incompleteness varies between different nonlife markets and affects the market competition to a large extent. Mature insurance markets with homogenous products are, in general, less incomplete than growing markets with less homogenous products. In growing markets the market players are concerned with expanding their shares of the market growth. Underlying reasons for growth may be general economic growth in the market and increased wealth, and therefore a need for consumers or businesses to reduce their individual risks to keep up their investments. Another reason may be new insurance needs generated by specific environmental changes in

the economy related to e.g., new legislation laws, new consumer articles or expanding business. According to [4], the players in any market have to position themselves in relation to five competitive forces: the rivalry among the existing competitors, the entry of new competitors, the bargaining power of buyers, the bargaining power of suppliers, and the threat of substitutes. The first three forces are in general the most important forces in the nonlife insurance markets and influence the profitability significantly. In mature insurance markets the competitive rivalry between the existing or incumbent insurers is more intensely related to capturing customers from each other compared to growing markets where the insurers compete more in attracting new customers into the market. Rivalry in price is common, but insurers also compete in product and service quality and variety, distribution and sales efficiency, brand identity, and other variables that are important for customers. It is crucial for insurers to optimize their business setup and insurance offers in relation to these competitive levers (*see Asset-Liability Management for Non-life Insurers*).

Barriers to insurance suppliers' entry into the market and barriers preventing customers from switching between suppliers are important competitive drivers and may arise from various sources. First, regulations that impose costs or conditions on entrants that are not imposed on existing suppliers in the market are a typical entry barrier. Regulation practice that delays supplier entrance may also diminish the competitive treat in the market. Second, switching barriers between the suppliers is particularly important for market competition. In nonlife insurance business there are most often 1-year contracts, even if the customers in general may switch from one insurer to another if the need for insurance ceases during the period, because e.g., the insured object is sold.

Nonlife insurance products are often complex and/or are purchased infrequently and hence difficult to compare. Hence, even if customers may switch their insurance company any time they want, the implication is still that customers often face high search costs of comparing insurance offers from different suppliers in the market. In general this has generated a demand in many markets for intermediaries who can help consumers and businesses to find their best insurance solutions and offers. In some markets, brokers or other intermediaries handle as much as 40% of the insurance market, where commercial

insurance lines in general have a higher broker share than the simpler and more commodity-based personal lines.

Other Market Characteristics

Moral hazard, adverse risk selection and uninsurable risks are three specific factors to take into account for insurance suppliers in a competitive market. *Moral hazard* (see **Moral Hazard**) occurs when insurance buyers are less careful in protecting their insured assets and/or cause financial loss to others because they know that an insurance company will bear the costs rather than themselves. Moral hazard may be reduced by use of deductibles and pricing incentives like no-claims discount or bonus-malus systems (see **Bonus–Malus Systems**) in motor insurance. [5] is a classical theoretical reference to moral hazard and its link to asymmetric information in insurance.

Adverse risk selection occurs when an insurance portfolio is made up of risks that are worse than average because the insurer has not set premiums according to individual risk levels and exposure. The premiums are rather set according to an average risk level in the portfolio or market that generates good value for high risks and bad value for low risks. Hence, low risks will leave the portfolio to get a better price offer at other places while high risks stay, and a mismatch between premium and risk level occurs in a negative spiral. In effect, imperfect information equilibrium has emerged between the insurer and the customers [6]; is a classical theoretical illustration of this equilibrium issue. The degree of adverse selection depends on the price sensitivity in the market and may be reduced by pricing the risks based on relevant and accurate risk information.

Uninsurable risks are risks that are impossible or at least difficult to calculate and that have some problems of adverse selection and/or moral hazard. Uninsurable risks are – by definition – unattractive to insurers, and sometimes more relevant for capital markets to acquire if the risks are large (like natural catastrophes, in some insurance markets). Insurable risks should have accidental and not intentional losses, and they should have economical feasible premiums, meaning that chance of loss must not be too high. Unemployment and a drop in property prices are examples of uninsurable risks.

Competitive Market Strategies

Diversified Strategies

Insurance suppliers have to relate closely to the market they operate in. As in all industries the strategic goal for a supplier in a nonlife insurance market is to gain value for shareholders and customers. To do so, the suppliers must select and build competitive domains with attractive characteristics. This is obviously more important in deregulated and highly competitive insurance markets than in regulated and less competitive markets. Anyhow, the general strategic challenge is to simultaneously balance long-term profitability and long-term market shares, that is, to balance loss and cost ratios and premium growth in terms of key performance indicators (see **Premium Calculation and Insurance Pricing**).

According to classical [4], long run above-average performance and sustainable competitive advantage should, in general, be generated from a differentiation strategy and/or a low cost leadership strategy. The competitive scope of both strategies could be broad range or narrow (niche) range to market segments. To outperform competitive rivals the chosen diversified strategy should better cope with the general market forces of existing competitor rivalry, new competitor entries and bargaining power of buyers. In nonlife insurance business there are three operative competitive levers, which are known as *winning core value skills* of an insurance company. These are pricing and underwriting, distribution and sales, and risk and capital management. Use of modern and up-to-date information technology is obviously also highly considerable, but only a tool to generate competitive advantages within each of the three operative levers. The following text briefly outlines the three levers from a *risk and market assessment* point of view.

Pricing and Underwriting

Insurance risk selection is a fundamental competitive driver in insurance markets, and risk pricing and underwriting the key levers to manage it. For all insurers it is important to avoid adverse risk selection by diversifying their risk pooling. Statistical information as well as experienced-based knowledge of the risk exposures and outcomes is therefore the basis on which to predict and price the risks. All suppliers in mature price-deregulated markets collect

risk information into data warehouse environments to make the information analytical and accessible. Existing suppliers with significant data information have an advantage compared with new market competitors without such information, even if new suppliers usually collect price information from existing ones to overcome this disadvantage when they enter the market. In personal insurance lines and small-to medium-sized commercial lines the state-of-the-art statistical method to price insurance risks is *generalized linear regression models*. Less data driven and more *a priori* engineering methods are more common when pricing risks in large commercial and industrial lines. The main reason behind this deviation in pricing methods is the difference in claims risk variability between the business lines. Private and small to medium commercial lines are, in general, characterized by a high number of standardized and independent types of risk exposure with typically a limited range of claim amounts and high claims frequency. Large commercial and industrial lines are, on the other hand, characterized by the opposite factors. In fact, nonlife insurance markets are very much affected by the specific combination of claims loss variability and average claims level in each market.

True market winners do not only price their insurance risks quite accurately, but also manage to identify and predict risk segments where the market in general makes profit and losses. They perform a combination of risk/cost pricing and market-based pricing, which makes it possible to optimize their insurance profitability based on tactical pricing and sales positions in the market. Unlike complete price sensitive markets – like e.g., efficient financial derivative markets – there exists no unique market price (which all market suppliers offer) for each unique individual risk in insurance markets. Thus, a differentiated market-based pricing strategy utilizes the market incompleteness where customers in addition to price preferences also have product, service and/or brand preferences. In effect, the degree of price sensitivity in market/customer segments in relation to product value proposition is important to take into account when using the pricing and underwriting lever as a strategic tool to optimize long-term insurance profitability. The insurance purchasing rate and portfolio retention rate may thus be included as stochastic estimation variables into a net present value based pricing model approach; see [7] for

more details. In summary, all market dynamic factors like growth, mobility and customer rotation are important elements that influence insurance companies significantly in their pricing and underwriting practice.

Distribution and Sales

Distribution-channel strategies in nonlife insurance markets are often conceived simply as a means to reach broad or narrow markets (based on the diversified strategic scope) and are seen as the mechanism to push products and services into the market. However, often the underlying risk selection effect varies significantly between the distribution channels. That is, the channel itself may be seen as an insurance risk selection dimension that may influence the pricing and underwriting substantially. It is, for example, well known that customers who buy their insurances through banking services typically and on average (all other factors equal) have lower claims risk than other customers because they, in average, have a better credit rate record (which is a significant, but controversial risk tariff factor in many markets). Equally, personal line homeowner and car insurances linked to real estate agencies and car dealers/manufacturers are not only examples of cost-efficient distribution strategies, but also show utilization of a positive risk selection effect in these channels.

There is a conglomeration of distribution strategies and setups in nonlife insurance business. The most common ones are independent agencies, brokers, direct service, bancassurance, retailers/white labels, real estate agencies, cars dealers/manufacturers, and other alliance partnerships. The mix of distribution models in a market depends very much on the characteristics of the specific market like growth, mobility, rivalry, and entry dynamics as earlier discussed. In addition the consumer behavior and insurance buying preferences in the market – like e.g., the penetration of telephone and internet as insurance sales and service communication tools – apparently also influence the choice of distribution strategy. New market entrants who build their business from scratch are often in a better infrastructural position to adopt new distribution opportunities and hence stress and scare existing and more traditional incumbent suppliers (see **Risk and the Media**).

Risk and Capital Management

Few businesses are as inherently risky in relation to their capital base as the nonlife insurance business. Reserve risk, premium risk, underwriting risk, operational risk, interest rate risk, equity price risk, credit risk, and investment risk are main risk categories which influence the key question: How much capital does the insurer need at the beginning of the year in order to be able to cover future financial liabilities with a specific percent as security? Enterprise risk management (ERM) has become an important centralized management approach to control the entire environmental risks that an insurance company faces. The key point is to have a simultaneous approach to all relevant financial risks at a business corporate level. By using dynamic financial analysis (DFA) techniques the insurers are able to model financial risk correlations and simulate statistical outcome effects to control the capital solvency security. The reinsurance program of a company is a key tool to appropriately adjust the security level, given all the risks that the company faces. Within the DFA approach, asset–liability management (ALM) is a way to allocate capital and return on equity demands down to each insurance line of business in the company.

Winning market performers govern ERM, DFA, and ALM within an optimized reinsurance setup. They use it as a competitive advantage to exploit hard markets faster and more fully than competitors with weaker capital cushion and worse solvency rating from rating agencies. In hard markets with struggling and negative earnings they do not need to increase their premium levels and/or downsize their expenses and businesses as much as their competitors. Risk and capital focused insurers are rather in a position to gain market shares through improved competitive price positions, improved internal cost, and service efficiency, and smart business investments.

Market Outlook and Trends

The nonlife insurance industry has been radically changed during the last decade. New insurance risks linked to climate change, air pollution, terrorism,

bird flu, nanotechnology, tinnitus, and electromagnetic fields have increased the general risk exposure of nonlife insurance business. Add to the general mixture the effects of globalization, deregulations, increased competition, changing demographics and pressures on margins, and it is quite obvious that the risk exposure will increase even more in the years to come. Technological innovation and commercialism; bancassurance and increased cross-financial services; increased cross-border mergers, acquisitions, and consolidations are also among the challenges which will continue to face the insurance industry in local as well as global markets; see [8] for further reading. In total, the general capability and management power of risk assessment will be a key lever to handle these challenges in an efficient and proper way.

Nonlife Loss Reserving

Risk Classification in Nonlife Insurance

JON HOLTAN

Nonlife Loss Reserving

The amount that an insurer must pay the insured as a result of a claim is known equivalently as claim amount or loss amount. Similarly, the payments that make up this amount are known indistinctly as claim payments or loss payments. Thus loss reserving is also known as *claims reserving*. In insurance terminology, a reserve is a fund, set aside from all other company's operations, to acknowledge (in the accounting sense) the impact of uncertainty in the financial position of the firm owing to its insurance operations. For example, specific reserves may be established to attribute a financial cost to pending claims, fluctuations in technical results, unearned premiums, and the value of investments. Among these, claims reserves are created with the purpose of paying all future benefits on already existing obligations, whether the specific claims are known or not. In other words, these reserves are a provision for all claims corresponding to events that have occurred but have not yet been completely settled [1].

Given the uncertainty involved in the financial value of such payments, reserving is clearly a problem of estimation or more precisely, forecasting. Together with ratemaking, the determination of claims reserves is one of the main responsibilities of nonlife actuaries, who, by certifying the adequacy of insurer's liabilities, help market participants to assess the following:

- the financial health of an insurer and its net worth;
- the *solvency* (see **Solvency**) of the company, after other considerations, such as liquidity, market value of assets, etc. are established;
- the insurer's profits during a specific period;
- the amount of incurred claims (paid claims plus reserves), as a tool for ratemaking (see **Insurance Pricing/Nonlife**).

To judge the adequacy of reserves, actuaries must base their calculations on both statutory and internal criteria, always keeping in mind that, as in all forecasting procedures, reserving depends crucially not only on the specific method employed, but also on the assumptions regarding all variables that will have an influence on the possible outcomes of the insurance business.

Given the substantial impact on companies' values as listed above, it is not surprising that different market participants will judge the relevance of both methods and assumptions under quite different perspectives. Insurance supervisors, having a macroeconomic perspective of the insurance industry, try to avoid companies becoming unable to meet their commitments, therefore they encourage the use of methods and assumptions that could produce relatively high values, to guarantee that a substantial portion of the insurers' resources is always available to absorb the fluctuations inherent to the business. In contrast, managers will be interested in keeping reserve levels to a minimum, in consideration of their company's risk profile, assuring policyholders (and stockholders) that obligations (and profit levels) will be met. Finally, reserving and ratemaking actuaries will be concerned with the accuracy of the forecast, producing results that will not only keep the insurer in business, but also that will generate data for setting rates for future underwriting periods.

Case Reserves and Gross IBNR

Once a claim is reported to the insurer, the company will regularly assess, on an individual basis, the amount of the insurer's liability until its final settlement. The total amount of these known and reported claims estimates is called the *case reserve* and is the first provision to be included in the total reserve requirement [2].

Nevertheless, case reserves are subject to future adjustments, and even claims that were considered settled, must sometimes be reopened for additional payments or to take recoveries into account. Furthermore, in many cases, incurred claims are still unknown to the insurer, because they have not been reported, i.e. they are incurred but not reported (IBNR) or they were possibly reported but have not yet been recorded. All these provisions for known and unknown claims, in addition to case reserves, are included in the gross IBNR reserve. The methods surveyed in the following sections should be considered applicable to the gross IBNR reserves.

A word of warning: even after employing methods that are sanctioned by the supervisors and judged appropriate by actuaries, financial analysts, accountants, and the management, a company could still build inadequate reserves. The final test relies on the accuracy of the forecast.

General Aspects of Loss Reserving Methods

The method to use in each situation depends on many factors: endogenous (those that can be controlled by the company) and exogenous (those that are determined by forces external to the company). Among the endogenous factors, the main ones are: specific risk for which the reserves are being calculated, the type and amount of data, size and nature of the insurance company, computing resources, and technical expertise of the person doing the estimation. The main exogenous factors are the macroeconomic and business environments, and the underwriting cycle [1].

The determination of claims reserves is generally a two-step process. The first involves the compilation of a suitable set of historical data, possibly classified according to the lines of business, as well as by the accident or underwriting year. The data will usually consist of one or more of the following: number of claims reported, the number settled, and the amounts paid. Sometimes, there will be a measure of exposure such as the number of units covered or total premiums earned. The underwriting experience will also be recorded as it evolves over time for groups of risks, preferably homogeneous. The second step consists of the selection from all projection methods available, which range from the very simple to the very sophisticated stochastic models.

Nonlife claims reserving methods are usually classified as stochastic (sometimes called *statistical*) and *nonstochastic* (also called *deterministic*), depending on whether or not they allow for random variation [1, 3]. The nature and complexity of the methods have been evolving over time along with the development of statistical methods, as well as computing power and software availability. Deterministic methods are usually based on various constants or ratios that are assumed to be known without error and are also assumed to remain valid in the future. Stochastic methods (*see Stochastic Control for Insurance Companies*), on the other hand, include explicitly the random variation that can be present in the components of the model, or they use a random error term that is meant to include all the unknown effects. The inclusion of a random component makes them amenable to formal statistical estimation and inference. Furthermore, stochastic methods have the advantage over deterministic

ones that it may be possible to generate probability distributions, and consequently probability intervals for unsettled claims. Using these methods, we can compute, in addition to the estimated values of the reserves, some traditional risk measures, such as value at risk (VaR) (*see Value at Risk (VaR) and Risk Measures*), Tail VaR, and others [3, 4].

We normally estimate reserves using data with some degree of aggregation or grouping. The calendar period when the claim occurs or is reported is called the *period of origin* or *accident period*, and all claims occurring within this period are analyzed as a group. These claims are then followed as they are paid over several development periods, until they are all ultimately paid out. We refer to accident and development years, but the arguments apply for any other reference periods or time units.

We use what is standard notation in claims reserving. Let X_{it} = amount of claims paid in the t th development year corresponding to accident year i , for $i = 1, \dots, k, t = 1, \dots, s$ where s = maximum number of development years it takes to completely pay out the claims corresponding to a given exposure or accident year. The X_{it} are known as *incremental claims values*. In addition to incremental claims, we usually define a corresponding set of cumulative claims $C_{ij} = \sum_{t=1}^j X_{it}, i = 1, \dots, k, t = 1, \dots, s$ [2, 3]. An important quantity is “ultimate claims”, which for accident year i is defined as $N_i = C_{is} = \sum_{t=1}^s X_{it}$ i.e., “ultimate claims” is the total amount of claims that will eventually be paid out, over all s development years for those claims corresponding to accident year i [2].

Deterministic Models

In the simplest deterministic case, claims are assumed to come from a homogeneous process that is stable over time, and in consequence, some kind of average of observed claims would be representative of what we should expect in the future. Possibly, the simplest deterministic claims reserving method, based on this type of assumption, is the loss ratio method. Loss ratio can be defined in various forms, but here we consider it as the ratio of the amount of “ultimate claims” to total premiums for a specific line of business. The loss ratio thus computed will necessarily be based on past experience of the company [1, 2]. The loss ratio estimate of the reserves on a given date is

obtained as Premium income $\times$ loss ratio – losses paid to date.

It has the advantage that it is very easy to apply, yet, in its simplest form, it ignores any structure that may be present in the data, such as trends, and there is no guarantee that the historical loss ratio will continue to be true in the future. Assessment of current trends and analysis can provide additional information that can be used to improve on the estimates. For an extensive description of loss reserving concepts and methods, see [1–3, 5].

However, there usually exists some additional information that should be taken into account in the estimation process. It is usually assumed that at least we know the accident and development year for each claim, and so we use this information to group the claims. In this respect, the next level of sophistication in the deterministic models would be to separate the claims belonging to different years of origin. That is, we separate the claims according to the period in which they were reported, or accident year, and see how their experience has behaved historically.

Specifically, for each accident year, we look at the total or ultimate claims paid and how they evolved over time, i.e., the pattern of payments established over the intervening years. Given the value of ultimate claims, C_{is} , for a known number m of accident years, $i = 1, \dots, m$, the pattern of accumulated claim payments can be written as a percentage of these ultimate claims. Using our notation, we compute $P_{it} = C_{it}/C_{is}$, $i = 1, \dots, m$, $t = 1, \dots, s$.

If we can show, for subsequent accident years, that the pattern of these percentages is stable, then they provide a means for arriving at an estimate of ultimate claims for future years. There are different ways in which the P_{it} can be applied to predict future claims. The most straightforward is to obtain

an average proportion for each development year $\bar{P}_t = \sum_{i=1}^m P_{it}$, $t = 1, \dots, s$. Hence, for any accident year i for which cumulative claims are known only up to development year $r < s$, ultimate claims may be projected as $\hat{N}_i^G = C_{ir}/\bar{P}_r$, and the corresponding estimated reserves as $\hat{R}_i = \hat{N}_i^G - C_{ir}$. This is called the *grossing-up* method [1]. Total reserves are then obtained by adding up estimated reserves over all the accident years where ultimate claims had not been reached.

The chain-ladder method is probably the mostly used claims reserving method. In its original form, it is deterministic, although there are some stochastic models that reproduce the same reserve estimates. It is also based on the assumption that the development pattern is stable, so that a constant proportion of ultimate claims is paid in each development year, irrespective of the year of origin. Usually, it is assumed that $k = s$ and that the available data are in the form of a triangle [1, 2]. In the notation given above, if the k th accident year is the most recent one, and there is information only on its first development year, then there will be information on two development years for claims in accident year $k - 1$, and so on, up to the first observed accident year for which there will be k development years observed and ultimate claims are completed in those k years. The triangle will be as in Table 1.

The data matrix is split into a set of known or observed variables (the upper left-hand part) and a set of variables whose values are to be predicted (the lower right-hand side). Thus we know the values X_{it} for $i + t \leq k + 1$, and assume all $X_{it} > 0$. The triangle of known values is called the *runoff triangle*. For ease of presentation, we have defined X_{it} to be incremental claims. The figures in the cells of the runoff triangle may represent

Table 1 Runoff triangle presentation of loss data

Year of origin	Development year						
	1	2	...	t	...	$k - 1$	k
1	X_{11}	X_{12}	...	X_{1t}		$X_{1,k-1}$	X_{1k}
2	X_{21}	X_{22}	...	X_{2t}		$X_{2,k-1}$	—
3	X_{31}	X_{32}	...	X_{3t}		—	—
⋮

different quantities: claim numbers, total payments (which can be viewed as weighted claim numbers), average payments etc. In addition, the figures can be cumulative or in incremental form. Usually, one form can be transformed into the other.

The chain-ladder method is based on the use of a set of link ratios F_{it} defined as $F_{it} = C_{it}/C_{i,t-1}$ that can be combined or weighted in various ways to obtain estimators for ultimate claims. Hence, the method is also known as the *link-ratio* method. In their most common formulation, they are used to compute development factors denoted by $\{f_j; j = 2, \dots, k\}$, defined as

$$f_j = \frac{\sum_{i=1}^{k-i+1} C_{i,j-1} F_{ij}}{\sum_{i=1}^{k-i+1} C_{i,j-1}} = \frac{\sum_{i=1}^{k-i+1} C_{ij}}{\sum_{i=1}^{k-i+1} C_{i,j-1}}, \quad j = 2, \dots, k \quad (1)$$

These factors are estimates of the growth (or decrease) in cumulative claims, between development years $j-1$ and j . Then, the chain-ladder technique estimates ultimate claims for accident year i as

$$\hat{N}_i^{CL} = C_{i,k-i+1} \cdot f_{k-i+2} \cdot f_{k-i+3} \cdot \dots \cdot f_k, \quad \text{for } i = 2, \dots, k \quad (2)$$

and outstanding claims (reserves) for the i th accident year as $\hat{R}_i = \hat{N}_i^{CL} - C_{i,i-k+1}$ or $\hat{R}_i = C_{i,k-i+1} \cdot (f_{k-i+2} \cdot f_{k-i+3} \cdot \dots \cdot f_k - 1)$ [1, 2]. Total reserves are again obtained by adding up estimated reserves over those accident years where ultimate claims had not been reached, i.e., for $i = 2, \dots, k$.

Example 1 The upper portion of Table 2 shows the development triangle of cumulative claims for a certain line of general insurance [2]. Application of equation (1) yields the development factors, f_j , shown in the last row of the table. These are applied successively for each accident year, as indicated in equation (2), to the last cumulative amount paid, $C_{i,i-k+1}$, which is in the main diagonal (in italics), to obtain $\hat{N}_i^{CL}$. This is the estimate of the amount that will ultimately be paid out for each accident year. These values are shown in the column corresponding to development year 5. They are then used to compute the required reserve for each accident year, $\hat{R}_i$. The total required reserve is \$60 184.

Variants of the method have been proposed, such as the Bornhuetter–Ferguson method, which uses external information to obtain initial estimates of ultimate claims for each accident year. This can be done by using loss ratios or alternative techniques. The estimates of ultimate claims are then combined with the development factors of the chain-ladder technique to estimate the required reserves [1, 2].

Deterministic claims reserving methods are relatively straightforward to apply and can easily be implemented in a spreadsheet. However, they have some drawbacks. They all assume a stable development pattern and, in their simplest form, the grossing-up and chain-ladder methods do not take possible trends into account. They can be modified to take into account these elements, but at the expense of their simplicity. The main disadvantage of all deterministic models, however, is that it is not possible to obtain variance estimates for the reserves.

Stochastic Methods

The increase in computing power, developments in statistical software, and the need to incorporate additional elements in the modeling and estimation of claims reserves, as well as the need to obtain measures of their variability, have gradually led to the development and implementation of stochastic methods. These methods add one or more stochastic elements to the claims reserving process. In essence, claims amounts or counts are considered as random variables, and models are specified to include as many components as necessary to take into account all the factors that influence the claims process, endogenous or exogenous. In addition, stochastic models allow the validity of the model assumptions to be tested statistically, and produce estimates not only of the expected value, but also of their variance [1, 3, 4, 6–9].

Like deterministic models, stochastic models usually assume a stable runoff pattern, at least initially. However, even if the past settlement pattern is reasonably stable, there may be considerable uncertainty regarding whether it will continue in the future. Another source of uncertainty is claims inflation. The provision to be held will also be affected by assumed investment earnings. In practice, it is seldom possible to do any better than suggest a fairly wide range, of not-unreasonable provisions, preferably in the form of probability intervals, based on different assumptions as to future claim inflation, investment earnings, etc., and possibly on different statistical methodologies. For an extensive description of stochastic loss reserving concepts and methods, see [1, 3, 4].

Some methods have been proposed that reproduce results from the chain ladder, while obtaining measures of their variability [7–10]. Others are intended to take advantage of formal statistical modeling and testing framework [6, 11–13]. One of the more widely used and general formulations is the following. Let the claims in the t th development year of accident year i , be represented by the random variable X_{it} (where $X_{it} > 0$), $i, t = 1, \dots, k$. We assume the data are in the form of a runoff triangle so that we have known observed values for $i + t \leq k + 1$.

Define $Y_{it} = \log(X_{it})$, and assume, in addition, that,

$$Y_{it} = \mu + \alpha_i + \beta_t + \varepsilon_{ij} \quad \varepsilon_{ij} \sim N(0, \sigma^2) \quad (3)$$

$i = 1, \dots, k, t = 1, \dots, k$ and $i + t \leq k + 1$, i.e., an unbalanced two-way analysis of variance (ANOVA) model. This was originally used in claims reserving by Kremer [11]; see also [1, 3, 12–14].

Thus X_{it} follows a lognormal distribution, and

$$f(y_{it} | \mu, \alpha_i, \beta_t, \sigma^2) = \frac{1}{\sigma \sqrt{2\pi}} \exp \left[-\frac{1}{2\sigma^2} \times (y_{it} - \mu - \alpha_i - \beta_t)^2 \right] \quad (4)$$

Let $T_U = (k + 1)k/2 =$ number of cells with known claims information in the runoff triangle; and $T_L = (k - 1)k/2 =$ number of cells in the lower triangle, whose claims are unknown that we want to estimate, to obtain the reserves. If $\underline{y} = \{y_{it}; i, t = 1, \dots, k, i + t \leq k + 1\}$ is a T_U -dimension vector that contains all the observed values of Y_{it} , and $\underline{\theta} = (\mu, \alpha_1, \dots, \alpha_k, \beta_1, \dots, \beta_k)'$ is the $(2k + 1)$ vector of parameters, then the Likelihood function can be written as

$$L(\underline{\theta}, \sigma | \underline{y}) = (2\pi)^{-T_U/2} \sigma^{-T_U} \exp \left[-\frac{1}{2\sigma^2} \sum_i^k \sum_t^k \times (y_{it} - \mu - \alpha_i - \beta_t)^2 \right] \quad (5)$$

where the double sum in the exponent is for $i + t \leq k + 1$, i.e., the upper portion of the triangle. From equation (5) we can obtain maximum-likelihood estimators of the parameters in $\underline{\theta}$ and, from these, generate estimates of the outstanding claims for the lower triangle along with their variances [4, 12–15]. Additional effects can be incorporated in the models at a cost of complicating them. Nevertheless, much richer information is obtained from the complete distribution of future claims [4, 14, 15].

Example 2 The upper portion of Table 3 shows the development triangle of incremental claims, X_{it} , for the same data as in Table 2. A special case of the model in equation (3) was also fitted to this data. For statistical and computational efficiency, μ and β_1 are set equal to zero [11, 14], but this does not affect the estimation of the reserves. Thus, maximum-likelihood estimators for the parameters were obtained for the model: $Y_{it} = \text{Log}(X_{it}) = \alpha_i + \beta_t, i = 1, \dots, 5, t = 2, \dots, 5$. They are given in Table 4.

Table 3 Incremental loss payments for a line of general insurance and reserves under the ANOVA linear regression model

Accident Year	Incremental loss payments (thousands of dollars)					Regression	
	Development year					Reserves	Standard error
	1	2	3	4	5		
1988	2000	4000	3000	2200	2800	–	–
1989	2600	4240	4080	4680	3956	3956	857
1990	2380	6580	5440	4408	4573	8981	1337
1991	3120	7680	5945	5232	5427	16 605	2140
1992	3800	8248	6800	5984	6207	27 239	3839
Total						56 782	5363

Table 4 Maximum-likelihood estimates of the parameters in model (3)

α_1	α_2	α_3	α_4	α_5	β_2	β_3	β_4	β_5
0.539	0.702	0.693	0.795	0.930	0.775	0.582	0.454	0.491

The estimated incremental claims for the lower triangle in Table 3 (shaded) are computed as $\hat{X}_{it} = \exp(\hat{\alpha}_i + \hat{\beta}_t)$ and then summed up by rows to obtain the reserves by accident year. These are given in the second to last column of the table. Total reserves are now \$56 782, somewhat smaller than those of the chain-ladder method. However, now we can obtain standard errors of the estimates using bootstrap or other methods [15]. The last column of Table 3 shows bootstrap standard errors. These may be used to obtain confidence intervals if the Normality assumption can be justified.

Further sophistication of the claims model allows the use of alternative distributions to the lognormal that is used in equation (4). One option is to model separately claim counts and average claims, i.e., let $X_{it} = N_{it} \cdot M_{it}$ where N_{it} is the number of closed claims and M_{it} is the corresponding average claim, both for the t th development year and corresponding to year of origin i . The estimates from the separate models can be combined to generate the distribution of future claims [14, 16, 17]. There is an advantage of using average claims, since more information is explicitly used in the modeling process and so the actuary can perform separate analyses for settled claims and for reported claims.

Statistical generalized linear models (GLMs) [18] can also be used in the claims reserving process, allowing us to use distributions other than the lognormal. This has been applied in claims reserving in [19, 20] by means of bootstrap methods to obtain the predictive distribution of outstanding future claims.

In fact, it can be shown that many of the existing models can be viewed as special cases of GLMs [21]. Other methods, such as the Kalman filter [22], have also been used to include additional structure in the models, as well as to provide the complete predictive distribution of future claims.

An alternative approach to claims reserving is to use Bayesian statistical methods. In many cases Bayesian methods can provide analytic closed forms for the predictive distribution of the variables involved, e.g., outstanding claims, and predictive inference is then carried out directly from this distribution and any of its characteristics and properties, such as quantiles, can be used for this purpose. However, if the predictive distribution is not of a known type, or if it does not have a closed form, then it is possible to derive approximations by means of Monte Carlo (MC) simulation methods. One alternative is the application of direct MC, where the random values are generated directly from their known distribution [14]. In recent years, the application of MC methods in loss reserving has developed extensively, in particular with the introduction of Markov chain Monte Carlo (MCMC) techniques [16, 17, 19, 23].

Bayesian methods and simulation techniques were also applied to the data of the two previous examples to generate the complete predictive distribution of future claims (in the lower triangle), Figure 1. This distribution has a mean equal to \$61 073, which should be compared with the reserves estimated by the other two methods.

Figure 1 Predictive distribution of total claims obtained by Bayesian methods and simulation

Nonparametric Calibration of Derivatives Models

In financial markets, a derivative is a security whose price depends on the price of one (or more) underlying security (or securities). The most prominent example may be an S&P 500 index option, whose price depends on the S&P 500 index. While the price of the underlying security is subject to supply and demand, the price of the derivative is largely driven by arbitrage: trades that take advantage of relative price cheapness or richness against the underlying. As a result of arbitrage, the price of the derivative becomes essentially predictable if the price of the underlying is given. Nonetheless, it is not necessarily a trivial business to gauge the relative price cheapness or richness of derivatives, particularly for exotic derivatives. To consistently price and effectively hedge various exotic and ill-liquid derivatives, we use mathematical models.

A derivatives model consists of postulated price dynamics of the underlying security (or securities). The postulations are based on our understanding of price behavior of the underlying security in the past. With a model, we can price various derivatives and calculate the price sensitivities with respect to various risk factors. The premise, however, is that the model can price correctly a selected set of derivatives that dominate liquidity. These derivatives, typically consisting of standard European call and put options, are called *benchmark derivatives*. Calibration, in general, means a procedure to pin down model coefficients by reproducing the market prices of benchmark derivatives (and perhaps other inputs). The prices of the benchmark derivatives are believed to carry information on the dynamics of the underlying security for the future.

Model users usually have options between a parametric and a nonparametric calibration. Under the parametric calibration, model coefficients take the form of parametric functions, which arise from empirical findings, of time and/or state variables. Under the nonparametric calibration, on the other hand, model coefficients are expanded into a set of basis functions, e.g., piece-wise constant functions. The parameters or the expansions are determined

through a trial-and-error procedure that eventually reproduces the input prices.

It is a trade-off in choosing between these two types of calibrations with regard to efficiency, robustness, and accuracy. Because the number of parameters to solve for is small, parametric calibrations can often be executed instantly, but fitting accuracy may be fair or even poor. Nonparametric calibrations, however, can achieve higher fitting accuracy at the price of solving for a bigger number of expansion coefficients. The choice for either approach is made on the basis of practical considerations. When fitting accuracy is important, which is often the case for a liquid option market (e.g., S&P 500 index options and London Interbank Offer Rates (LIBOR) derivatives), preference is given to nonparametric calibration.

In this article, we describe nonparametric calibration technologies for equity option model and for the LIBOR market model. The former model has a single state variable, while the latter model has many. With these established technologies, we show that nonparametric calibrations in finance are far from plain applications of standard optimization routines, instead, they require delicate mathematical modeling and careful analysis.

Reconstructing Local Volatility Surface for Equity Derivatives Models

Under the deterministic volatility model for equity options, a stock price, S_t , is assumed to follow a continuous one-factor diffusion process

$$\frac{dS_t}{S_t} = (r_t - q_t) dt + \sigma(S_t, t) dW_t \quad (1)$$

where W_t is a Brownian motion under the pricing measure, r_t the interest rate, q_t the dividend yield, and $\sigma(S, t) : \mathbb{R}^+ \times [0, \tau) \rightarrow \mathbb{R}$ is a smooth and bounded deterministic function (so a unique solution to equation (1) exists). For an option with payoff $f(S_T, T)$ (to occur at time $T \leq \tau$), its time- t value, $V(S_t, t)$, satisfies the celebrated Black–Scholes–Merton equation [1]:

$$\begin{aligned} \frac{\partial V}{\partial t} + (r_t - q_t)S \frac{\partial V}{\partial S} + \frac{1}{2} \sigma^2(S, t) \frac{\partial^2 V}{\partial S^2} - r_t V &= 0, \\ V(S, T) &= f(S, T) \end{aligned} \quad (2)$$

The current option value, $V(S_0, 0)$, can be solved numerically, e.g., through a lattice method [2].

Calibration of this model is an inverse problem: given a set of market prices of options, we try to determine the volatility function, $\sigma(S, t)$. According to Dupire [3], $\sigma(S, t)$ could be calculated explicitly if we had market prices of call options for continuums of strike and maturity. This is, however, not the case. In reality, we only have the prices of around-the-money call/put options for a few maturities. The conventional approach to find a reasonably smooth $\sigma(S, t)$ is to adopt and then minimize an objective function (that regulates the smoothness of $\sigma(S, t)$) under the price constraints. This approach, however, is considered too slow for production use.

One favored approach [4] that works quite well is to use a two-dimensional spline functional to represent the local volatility function. We take $p \leq m$ spline knots, $\{(s_i, t_i)\}_{i=1}^p$, in the region $[0, \infty) \times [0, \tau]$. Given the values of the local volatility surface at those knots, $\{\sigma_i = \sigma(s_i, t_i)\}_{i=1}^p$, we uniquely define the local volatility surface through cubic spline interpolation (using certain spline end conditions). An option is then priced using the local volatility surface. Calibration is achieved by solving the following problem:

$$\begin{aligned} \min_{\{\sigma_i\}} \sum_{j=1}^m w_j [V_j(S_0, 0; \{\sigma_i\}) - \bar{V}_j]^2 \\ \text{subject to } l \leq \sigma_i \leq u, \quad \forall i \end{aligned} \quad (3)$$

where $\{V_j(S_0, 0; \{\sigma_i\})\}$ are option values calculated using a lattice method, $\{\bar{V}_j\}_{j=1}^m$ are market prices of the options, and $\{w_j\}$ are positive weights, which allow users to place importance on each input price according to liquidity or other considerations. Problem (3) can be solved efficiently by standard minimization algorithms.

This approach achieves a smooth solution through cubic spline interpolations, and thus avoids using a smoothness regularization. Note that the deterministic volatility model enjoys certain degree of popularity because of its intuitiveness, although there is a continuing debate in the industry over the performance of the model.

Reconstructing Local Volatility Surface for LIBOR Market Model

LIBOR market model is considered the benchmark model for interest-rate derivatives. Let $f_j(t)$ be the arbitrage-free forward lending rate (for simple compounding) seen at time t for the period (T_j, T_{j+1}) , the LIBOR market model takes the form

$$\begin{aligned} df_j(t) = f_j(t) \gamma_j(t) \cdot (d\mathbf{W}_t - \sigma(t, T_{j+1}) dt), \\ 1 \leq j \leq N \end{aligned} \quad (4)$$

where W_t is a multidimensional Brownian motion under the pricing measure, $\gamma_j(t)$ is the volatility of $f_j(t)$, and $\sigma(t, T_{j+1})$, the volatility of the T_{j+1} -maturity zero-coupon bond, is an explicit function of $\{\gamma_j(t)\}$ (see [5]). Note that $\gamma_j(t) = 0$ for $t \geq T_j$, as at $t = T_j$ the forward rate $f_j(t)$ is set (or fixed) and thus becomes “dead”. Calibration here means to specify $\{\gamma_j(t)\}$ by reproducing, typically, input prices of at-the-money (ATM) swaptions and forward-rate correlations.

A swaption is an option to enter into a swap, which is a financial contract to exchange interest payments, a fixed-rate stream for a floating-rate stream. The floating rate is indexed to, typically, a par yield in the LIBOR market. The swaption for a future period, say (T_m, T_n) , can alternatively be priced as a series of contingent cash flows, $\Delta T_j (R_{m,n}(T_m) - K)^+$, to occur at T_j , $j = m + 1, \dots, n$, where $\Delta T_j = T_{j+1} - T_j$ is the j^{th} accrual interval, K is the prespecified fixed rate for the underlying swap, and $R_{m,n}(t)$ is the time- t prevailing swap rate (or par yield) for the period (T_m, T_n) , given by

$$R_{m,n}(t) = \sum_{j=m}^{n-1} w_j(t) f_j(t) \quad (5)$$

with

$$w_j(t) = \frac{\Delta T_j P(t, T_{j+1})}{A_{m,n}(t)} \quad (6)$$

Here, $P(t, T_{j+1})$ is the discount factor for cash flows occurring at T_{j+1} , and

$$A_{m,n}(t) := \sum_{j=m}^{n-1} \Delta T_j P(t, T_{j+1}) \quad (7)$$

is the value of an annuity. The payoff of the option at time $t = T_m$ is thus

$$V(T_m; T_m, T_n, K) = A_{m,n}(T_m) \cdot \times (R_{m,n}(T_m) - K)^+ \quad (8)$$

In the LIBOR market, swaptions are priced using Black's formula:

$$V(t; T_m, T_n, K) = A_{m,n}(t)[R_{m,n}(t)N(d_+) - KN(d_-)] \quad (9)$$

where $N(\cdot)$ is the standard normal accumulative function,

$$d_+ = \frac{\ln \frac{R_{m,n}(t)}{K} + \frac{1}{2} \bar{\sigma}_{m,n}^2 T_m}{\bar{\sigma}_{m,n} \sqrt{T_m - t}} \quad (10)$$

$$d_- = d_+ - \bar{\sigma}_{m,n} \sqrt{T_m - t} \quad (11)$$

with

$$\bar{\sigma}_{m,n}^2 = \frac{1}{T_m - t} \sum_{j=m}^{n-1} \sum_{k=m}^{n-1} w_j(t) w_k(t) \times \int_t^{T_m} \gamma_j(s) \cdot \gamma_k(s) ds \quad (12)$$

In the market, the swaption price $V(t; T_m, T_n, K)$ can be observed, and is quoted using $\bar{\sigma}_{m,n}$, the so-called implied (Black's) volatility of the swaption. When $n = m + 1$, $R_{m,m+1}(t) = f_m(t)$, i.e., the swap rate reduces to a forward rate, and the swaption reduces to an option on $f_m(t)$, called a *caplet*, which is also actively traded. Owing to the one-to-one correspondence between the to the dollar price and its implied volatility, the problem of calibrating the LIBOR model can be equivalently stated as follows: given

1. implied volatilities, $\{\bar{\sigma}_{m,n}\}$, for a set of ATM swaptions (including caplets); and
2. correlation matrices for forward rates, $\{\mathbf{C}^i = (C_{jk}^i)\}$,

determine $\{\gamma_j(t)\}$ so that both the implied volatilities and correlation matrices are matched.

Under the nonparametric approach, we look for piece-wise constant volatilities of the form

$$\gamma_j(t) = \gamma_j^i = s_{i,j}(a_{j,1}^i, a_{j,2}^i, \dots, a_{j,n}^i)^T =: s_{i,j} \mathbf{a}_j^i, \quad \text{for } t \in [T_{i-1}, T_i), \quad 1 \leq i \leq j \leq N \quad (13)$$

with

$$s_{i,j} = \|\gamma_j^i\|_2 \quad (14)$$

and

$$\|\mathbf{a}_j^i\|_2 = 1 \quad (15)$$

In terms of $\{s_{i,j}\}$, equation (12) becomes

$$\bar{\sigma}_{m,n}^2 = \frac{1}{m} \sum_{i=1}^m \sum_{j,k=m,n-1} s_{i,j} s_{i,k} (w_j w_k C_{j,k}^i) \quad (16)$$

while correlation matching implies that there should be

$$(\mathbf{a}_j^i)^T \mathbf{a}_k^i = C_{jk}^i, \quad i \leq j, k \leq N \quad (17)$$

As already seen, the equations for $\{\sigma_{i,j}\}$ and $\{\mathbf{a}_j^i\}$ are decoupled, and the solution of $\{a_j^i\}$ can be obtained readily from a Cholesky matrix decomposition of $\mathbf{C}^i$. The problem for $\{s_{i,j}\}$, however, is underdetermined and thus ill-posed.

To make the problem for $\{s_{i,j}\}$ well posed, we adopt a smoothness regularization

$$\min \|\nabla \mathbf{s}\|^2 + \epsilon \|\mathbf{s} - \mathbf{s}_0\|^2 \quad \text{for some } \epsilon > 0 \quad (18)$$

where $\|\cdot\|$ is the usual two norm and ∇ is the discrete gradient operator such that

$$\nabla s_{i,j} = \begin{pmatrix} s_{i,j} - s_{i-1,j} \\ s_{i,j} - s_{i,j-1} \end{pmatrix} \quad (19)$$

Therefore, to determine $\{s_{i,j}\}$, we solve equation (18) under the constraints equation (16). Note that the second term of the regularization function allows the use of *a priori* volatility surface, and it also ensures the positive definiteness of the objective function. Under matrix notations,

$$S = \begin{pmatrix} s_1 \\ s_2 \\ \vdots \\ s_N \end{pmatrix} \quad \text{with} \quad s_i = \begin{pmatrix} s_{i,i} \\ s_{i,i+1} \\ \vdots \\ s_{i,N} \end{pmatrix} \quad (20)$$

we can recast equation (18) and equation (16) into

$$\begin{aligned} \min_S & (S - \tilde{S}_0)^T A (S - \tilde{S}_0) \\ \text{s.t.} & \quad S^T G_{m,n} S = \tilde{\sigma}_{m,n}^2, \quad (m, n) \in \Lambda \end{aligned} \quad (21)$$

for some matrices A and $\{G_{m,n}\}$ with $A^T = A > 0$, $G_{m,n} = G_{m,n}^T \geq 0$, and a constant vector $\tilde{S}_0$. Here, Λ stands for the set of input swaptions. Note that equation (21) differs from a conventional quadratic programming problem in its quadratic instead of linear constraints. Because of that, conventional quadratic programming methodologies do not work for (21). Fortunately, such an unconventional problem can be

solved by the following strategy. We first superimpose a convex and monotonically increasing function to the objective function:

$$\begin{aligned} \min_S & U \left((S - \tilde{S}_0)^T A (S - \tilde{S}_0) \right) \\ \text{s.t.} & \quad S^T G_{m,n} S = \tilde{\sigma}_{m,n}^2, \quad (m, n) \in \Lambda \end{aligned} \quad (22)$$

where we can take, for instance, $U(x) = x^2$. Then, we solve equation (22) along the approach of the method of Lagrange multipliers. As a consequence of its additional convexity, the objective function now dominates the constraints, and equation (22) features a unique solution. Such a strategy takes full advantage of the quadratic functionality in both objective function and constraints. In fact, on the basis of the Lagrange multiplier method, we can develop a Hessian-based descending algorithm, in which each descending search is achieved by solving a symmetric eigenvalue problem, and thus renders an algorithm fast enough for production use. We refer to [6] for the details of the solution procedure and analysis. Figure 1 shows the local volatility surface constructed using the sterling pound data of February 3, 1995.

Nuclear Explosion Monitoring

Risk Analysis in Explosion Monitoring

Because the ramifications of misidentifying an explosion are so serious, seismologists and statisticians who monitor for nuclear explosions follow a near mantra that begins with the commitment to “miss no explosions”. Declaring an explosion to be an earthquake is a profoundly serious mistake by itself, but assigning a cost to this error is untenable from a nuclear explosion monitoring point of view. The cost of misidentifying an explosion could be political, financial, environmental – or most serious, the loss of life – and may not be realized for decades. The cost of declaring an earthquake to be an explosion is an operational burden that is also difficult to quantify because the reasons for making the error can vary greatly, dramatically changing the subsequent data collection and analysis. This focus on correct identification makes risk quantification in nuclear explosion monitoring unique. Risk quantification in this setting does not explicitly declare costs for decisions although costs are implicit in the Bayesian classification methods. The commitment to never misidentify historical explosions drives the prior-to-data probability that an event is an explosion to be high, regardless of the geophysical location or time frame of an event. The question of performance then centers on false alarms and the associated operational burden.

In the seismic context, the approach to identifying an unknown event begins as an examination of the seismograms of the event recorded at many locations. A seismogram is the stream of ground motion data observed by a sensor. Regional stations relatively close to the event and long-range or teleseismic stations produce seismograms similar to those shown in Figure 1, in this case from a regional station. The next step is to extract a set of seismogram features that have previously been determined as useful for discriminating between earthquakes and explosions. They are nearly always related to characteristics of the early arriving body wave or P phases and the later arriving shear or S phases, labeled in Figure 1. It is clear from this straightforward example that characteristics of the relative amplitudes or frequencies of the P or S phases might be sufficient

for discriminating between these particular events. However, the distinctions can become quite obscure for many events and additional discriminating features are needed (see, for example [1–3]).

Likelihood-Based Characterizations of Risk

The discriminating features are either continuous or categorical variables that are extracted from a collection of seismograms. Examples include event hypocenter (latitude, longitude, and depth) and the ratio of two different magnitude measures. Seismologists need the ability to examine summary statistics from the discriminants separately because there are features that can be used to unequivocally rule out the event as an explosion. For example, locating the event in the ocean or in an unlikely testing region with high confidence provides strong evidence against the explosion hypothesis. Estimated depths of greater than 20 km also provide strong evidence against the event being an explosion. There is the strong possibility that only a small number of discriminants will be observed. Therefore, a critical component of the system is a measure that allows an analyst to evaluate the discriminants one at a time in the general process of ruling out explosions.

To summarize the analysis, the data (discriminants) used to make a decision as to whether an explosion can be ruled out come as a set of potentially incompletely observed discriminants, say $D_1, D_2, \dots, D_n$. Conceptually, we assume that these are random variables with a given joint distribution that can either be developed from a model or estimated from empirical data. The decision to concentrate on ruling out explosions has led the explosion monitoring community to focus on the null hypothesis H_0 that the event is an explosion. Technical evidence is then sought to disprove this hypothesis. Suppose that, in any given case, we observe a value d_i for a particular discriminant. The p value is defined in the usual way for this single discriminant, that is, as $P_i = \text{Prob}\{D_i > d_i | \text{explosion}\}$, assuming that large values of the discriminant lead to small p values, and therefore, to rejection of H_0 , the explosion hypothesis. The seismologist looks at the collection of p values, regarding them singly as evidence against the explosion hypothesis when they are small.

Although it may be sufficient in many cases to use the collection of p values, $P_i, i = 1, \dots, n$, to

Figure 1 A nuclear explosion from the Nevada test site compared to a nearby earthquake as recorded from regional distances. These two are easily distinguished and do not represent the difficulties that arise when discriminating in general

make a decision, the overall risk may be reduced by combining the individual values to obtain an overall discriminant score and associated p value. A linear discriminant analysis (*see Credit Scoring via Altman Z-Score*) using raw waveform measurements as discriminants has been the historical approach to handling this problem (see, for example [4–6]).

In [7], a linear–quadratic discrimination compromise using regularization is proposed for seismic discrimination. In [8], arcsine transformed p values as inputs to discriminant analysis is proposed (the arcsine transformed p values (Y_i) are called *standardized discriminants*). Standardized discriminants are approximately normally distributed, and are unitless and comparable from event to event and across geographical regions. The theoretical properties of p values (standardized discriminants) as discrimination features is an open research question. The advantages they provide for uniformity in scaling and treating categorical inputs seem persuasive. The event classification matrix (ECM) analysis proposed in [8] includes reporting individual discriminant p values, multivariate discrimination scores, and posterior classification probabilities for each event under analysis.

Because the historical data set cannot be an exhaustive one, an event may be dissimilar enough from historical events that no decision can be made, and further investigation is warranted. As such, the capability to make a *no identification* decision

is integral to the process. Conceptually, we may illustrate the possible decisions as in Figure 2 for two observed discriminants d_1 and d_2 leading to transformed p values Y_1 and Y_2 . Each panel shows the joint distributions of the two transformed p values along with their projections on the two dimensional Y axis. Typical observations leading to classification into the categories (a) explosion, (b) earthquake, (c) indeterminate, and (d) unidentified are shown in Figure 2. The distinction between indeterminate and unidentified is that indeterminate is on the boundary between known distributions and we are unable to make a decision, whereas unidentified is inconsistent with both of the event categories.

Discriminants Used in Explosion Monitoring

The first four discriminants given below are well established for monitoring from teleseismic distances (greater than 2000 km). The physical basis for these discriminants is discussed at length in the literature (see [1, 9–11]). The details for a statistical formulation of these discriminants is in [8]. Recently, the necessity for monitoring at regional distances (less than 2000 km) has stimulated renewed interest in using data from regional arrays. The last feature is an example of a useful regional discriminant that

Figure 2 Illustration of likelihood functions showing observed events that would be classified into the four categories (a) explosion, (b) earthquake, (c) indeterminate, and (d) unidentified

can lead to improved methods of classification from regional data (for example, see [2, 3, 10]).

Location, Depth

The combined costs and limitations of mining and drilling technology make deep underground explosions very unlikely. As a part of standard processing, all earthquakes and potential explosions are located with a confidence region using a nonlinear least-squares model. P-wave arrival times at each of the seismometers are related nonlinearly with a travel time model to a common latitude, longitude, and depth (hypocenter). If the event is located with high confidence in an area where testing is unlikely, one may discount the explosion hypothesis. If z is the true depth and z_0 is the critical depth beyond which

an explosive source can be buried, the null hypothesis consistent with explosion characteristics is $H_0 : z \leq z_0$. The likelihood ratio test for $z = z_0$ yields a monotone function of a t -statistic. The p value is simply the tail probability of a central t -distribution calculated from the observed value of the test statistic. A small p value leads to an inference inconsistent with H_0 ; a large one leads to the inference consistent with H_0 .

Reflected pP Depth Phase

The P wave travels directly from a teleseismic disturbance to a seismic station. In contrast, the pP wave is a reflected P wave that travels from the teleseismic disturbance to the earth's surface before being reflected to the station. For a single seismic

station, the arrival time delay between the P wave and pP wave is a function of event depth. Explosions and shallow earthquakes (SEQs) produce very short time delays across a network of stations and the pP waves are therefore very difficult to detect. The pP wave from a deep earthquake (DEQ) is more readily detected across a network of stations because of longer delay times that exhibit a systematic relationship with distance to the event. Observed pP waves with a systematic pattern of delays *versus* distance is counted as evidence against the null hypothesis that the event is shallow (e.g., an explosion). The statistical model providing the depth phase discriminant is a compound one that combines (a) the number of observed pP waves with (b) a measure of the systematic behavior of delays.

Surface-Wave Energy

The ratio of body wave energy to surface-wave energy is based on the physics that earthquakes at depths less than roughly 50 km excite relatively more surface-wave energy than a single-shot explosion. In log units, the null hypothesis consistent with explosions is that the surface wave magnitude (M_S)

is less than the body wave magnitude (m_b), that is, $H_0: M_S - m_b \leq \Delta_0$. A small p value leads to the inference inconsistent with H_0 ; a large one leads to the inference consistent with H_0 .

Several different estimators for surface-wave energy exist, ranging from the 20-s waves originally proposed by Marshall and Basham [11] to the recent 7-s waves investigated by Bonner *et al.* [12], which are available for regional events like those shown in Figure 1. Figure 3 shows 40 SEQs and 126 explosions in the western United States presented in [12]. Note the good separation between the earthquake and explosion populations.

Polarity of First Motion

The direction of the first prominent cycle of the P-wave arrival or *polarity* is a useful discriminant because the energy of an underground single-shot explosion produces upward P-wave energy at a seismometer, regardless of its location. In contrast, an earthquake can produce both upward and downward P-wave arrivals across a well-dispersed global network of stations. If the polarity is upward at all stations, then the discriminant is not used because

Figure 3 Plot of M_S versus m_b discriminant values for 40 shallow Western United States earthquakes and 126 explosions. The scores are based on the likelihood-ratio criterion, derived assuming regressions with equal slopes and unequal intercepts. Equal prior probabilities were assumed for the two populations [Reproduced from [12]. © Seismological Society of America, 2003.]

station configuration may play a role in observing only upward polarity. The model for the polarity discriminant also includes the probability of correctly identifying the direction of first motion, which is often quite difficult.

Relative Energy in Regional P and S Frequency Bands

The two events in Figure 1 suggest that the amplitudes and short-term spectra of the P and S phases behave differently for explosions and earthquakes. In particular, the ratio of P to S power integrated over the frequency band 4–8 Hz turns out to be larger for explosions than for earthquakes. Hence the logarithms of the ratio of P to S spectra can be used as a discriminant.

An Example: The Event Classification Matrix (ECM)

The hypothesis-testing framework results in discriminant p values that are unitless and comparable from event to event and across geographical regions. Also, because a p value is derived from an observed discriminant, it may be viewed as a discriminant. ECM analysis uses this dual interpretation of p values.

Risk management begins with the prior probabilities that an event is an earthquake or explosion. Combining the priors and the likelihoods of standardized discriminants (Y_i) with Bayesian classification methods (see **Statistics for Environmental Toxicity**) yields an estimate of the posterior probabilities that an event is an earthquake or an explosion. Examining how posterior classification probabilities are modified by the data provides useful input to forensic analysis.

The individual discriminant p values, and a combined analysis with standardized discriminants that in part gives posterior probabilities comprise ECM analysis. Tables 1 and 2 demonstrate how the ECM may be used to communicate the individual discriminant p values and subsequent Bayesian decision. Table 1 shows ECM results from a SEQ with body wave magnitude 5.32 that occurred near the border between Uzbekistan and Turkmenistan. Table 2 shows results from a DEQ with body wave magnitude of 5.39 in the Andes mountains region of Argentina.

The hypocenter depth discriminant for the shallow event returns a p value of 0.96, a clear indication that the event is shallow, and thus consistent with both SEQs and explosions. Conversely, the surface-wave energy discriminant strongly rejects the explosion hypothesis with a p value of 0. Note that neither the reflective phase nor first motion discriminants are available for this event, yet a decision can

Table 1 ECM results for shallow earthquake (SEQ) in south central Eurasia

Discriminant	Explosion hypothesis	p value
Hypocenter depth	$H_0 : \text{depth} \leq z'_0$	0.96
Reflective phases	$H_0 : \text{no observed } pP$	Not observed
Surface-wave energy	$H_0 : \tilde{M}_S - \tilde{m}_b \leq \Delta_0$	0.00
Polarity of first motion	$H_0 : \text{single point explosion}$	Not observed
Posterior probability: $P(EX) = 0.083 : P(SEQ) = 0.914 : P(DEQ) = 0.001$		

EX: explosion

Table 2 ECM results for deep earthquake (DEQ) in Argentina

Discriminant	Explosion hypothesis	p value
Hypocenter depth	$H_0 : \text{depth} \leq z'_0$	0.00
Reflective phases	$H_0 : \text{no observed } pP$	0.19
Surface-wave energy	$H_0 : \tilde{M}_S - \tilde{m}_b \leq \Delta_0$	0.23
Polarity of first motion	$H_0 : \text{single point explosion}$	0.00
Posterior probability: $P(EX) = 0.0 : P(SEQ) = 0.064 : P(DEQ) = 0.934$		

EX: explosion

still be made with high confidence. Assigning prior probabilities of 0.333 for the three populations yields an estimated posterior probability of 0.914 that the event is a SEQ.

All four discriminants were observed for the second event and show that the p -value interpretation must be taken in the context of a discrimination feature rather than simply as a hypothesis test result. The hypocenter depth discriminant strongly indicates a deep event, while the first motion discriminant strongly indicates an earthquake. The surface-wave energy and reflective phase discriminants offer some contradictory evidence but are not strong enough to result in an indeterminate solution. The posterior classification rule clearly identifies (again, correctly so) the event as a DEQ with posterior probability 0.934.

In terms of forensic analysis, an important feature of the ECM is the ability to observe the behavior of each discriminant as well as the overall posterior classification results. If there is any ambiguity in the result, the individual discriminants can be used to determine where to begin the forensic investigation.

Discussion

We have summarized some of the rather unique features of the explosion monitoring problem that have led to using the ECM as an aid for making risk-adverse decisions. First, the use of features one at a time is motivated by the knowledge that several of them provide unequivocal evidence that can rule out explosive origins without proceeding to a consideration of other features. In cases where this is not possible, discriminant analysis can be used to combine the features into a summary giving both an overall explosion p value and the posterior probability that the event was an explosion. The investigator still retains the option for interpreting the results in a political context.

The core problem in explosion monitoring is screening the many events that occur everyday. The fact that overall p values are computed for a very large number of events suggests that their empirical distributions can be utilized to control the false discovery rate (FDR) (see **Microarray Analysis; Digital Governance, Hotspot Detection, and Homeland Security**). In the context of seismic identification, the FDR is defined as the ratio of

false alarms to detections (see [13]). A false alarm is mistakenly identifying an event as an explosion, whereas detection is correctly identifying the event as an explosion. Hence, the above approach to simultaneous testing for multiple events also benefits from summaries in terms of p values.

Acknowledgment

The authors acknowledge the support of Ms. Leslie A. Casey and the National Nuclear Security Administration Office of Nonproliferation Research and Development for funding this work. This work was completed by Pacific Northwest National Laboratory under the auspices of the US Department of Energy, under contract DE-AC05-RLO1830. We gratefully acknowledge the Editor, Dr. Edward Melnick for comments that improved the clarity of the final version of the paper.

Numerical Schemes for Stochastic Differential Equation Models

Background

Stochastic differential equation (SDE) models are now widely used to describe quantities whose current value is known, but whose future value is uncertain. Typically, nonlinear SDEs cannot be solved analytically, and hence approximate solutions must be obtained from numerical simulations. The design and analysis of numerical methods for SDEs is quite subtle, but the field has matured to the extent where many schemes are available and their approximation properties are well understood [1–3].

Black–Scholes Asset Price Model

The simplest nontrivial stochastic differential equation model for asset price movement takes the form

$$dS(t) = \mu S(t) dt + \sigma S(t) dW(t) \quad (1)$$

Here, $S(t)$ represents the asset price at time t , and we assume that the time-zero asset price, $S(0)$, is known. The solution $S(t)$ is a stochastic process – in other words, $S(t)$ is a random variable at each time point, t . This model involves a Brownian motion, $W(t)$, and two constant parameters.

- μ : the parameter μ is called the *drift* or *expected growth* of the asset, because $\mathbb{E}[S(t)] = S(0)e^{\mu t}$.
- σ : the parameter σ is called the *volatility*. It governs the second moment of the asset price in the sense that $\mathbb{E}[S(t)^2] = S(0)^2 e^{(2\mu + \sigma^2)t}$.

In the case where $\sigma = 0$, there is no randomness in equation (1) and the model simply describes compound interest for a bank deposit under a constant interest rate μ . Hence, we may view equation (1) as modeling a situation where the “rate of return” is uncertain. This simple model has proved extremely useful for describing a wide range of financial assets, and forms the basis of the classic Black–Scholes option valuation theory [4–6]. It is tractable in the

sense that an explicit solution is available:

$$S(t) = S(0)e^{\left(\mu - \frac{1}{2}\sigma^2\right)t + \sigma W(t)} \quad (2)$$

Using the defining properties of Brownian motion, we can simulate solution paths by discretizing a time interval $[0, T]$ into subintervals of length $\Delta t = T/N$ and letting $t_i = i\Delta t$. Then the asset price $S(t_i)$ evolves into the asset price $S(t_{i+1})$ according to

$$S(t_{i+1}) = S(t_i)e^{\left(\mu - \frac{1}{2}\sigma^2\right)\Delta t + \sigma\sqrt{\Delta t}Z_i} \quad (3)$$

where the $\{Z_i\}$ are independent random variables with the standard normal distribution.

In MATLAB [7], we could compute and plot a discretized solution path as follows:

```
>> T = 1; N = 100; Dt = T/N; mu = 0.06;
sigma = 0.25; Szero = 1;
>> Spath = Szero*cumprod(exp((mu-sigma
^2)*Dt+sigma*sqrt(Dt)*randn(N,1)));
>> plot(Spath)
```

Figure 1 shows fifty such paths – in each case, the discrete points $(t_i, S(t_i))$ are joined to give a piecewise linear curve. It follows from equation (2) that $S(t)$ is lognormally distributed. In particular, at the final time $t = T$, the asset price has density given by

$$f(x) = \frac{\exp\left(\frac{-\left(\log\left(\frac{x}{S_0}\right) - \left(\mu - \frac{\sigma^2}{2}\right)T\right)^2}{2\sigma^2 T}\right)}{x\sigma\sqrt{2\pi T}}, \quad \text{for } x > 0 \quad (4)$$

with $f(x) = 0$ for $x \leq 0$. As confirmation, Figure 1 is the final asset prices $S(T)$ for 10^5 discrete asset paths, with the density $f(x)$ superimposed as a dashed line.

Simulating General Stochastic Differential Equation Models

The simple model (1) has been modified and extended in many directions as researchers have attempted to produce more realistic descriptions of particular

Figure 1 Asset price paths and a histogram at expiry time

financial objects. For example, the *mean-reverting square root process*

$$dS(t) = \lambda (\mu - S(t)) dt + \sigma \sqrt{S(t)} dW(t) \quad (5)$$

where λ , μ , and σ are positive constants, was originally proposed by Cox *et al.* [8] to describe interest rates, but now features in many other models. In this case, the noise coefficient scales with the square root of the asset value, when $S(t)$ is large, this is often more realistic than using the linear scaling in equation (1). For this SDE we have

$$\mathbb{E}[S(t) - \mu] = e^{-\lambda t} (S(0) - \mu) \quad (6)$$

and

$$\begin{aligned} \mathbb{E} \left[S(t)^2 - \mu^2 - \frac{\sigma^2 \mu}{2\lambda} \right] &= \left(2\mu + \frac{\sigma^2}{\lambda} \right) \\ &\times (S(0) - \mu) e^{-\lambda t} \\ &+ \left(S(0)^2 + \left(\mu + \frac{\sigma^2}{2\lambda} \right) \right. \\ &\times \left. (\mu - 2S(0)) \right) e^{-2\lambda t} \end{aligned} \quad (7)$$

so that

$$\lim_{t \rightarrow \infty} \mathbb{E}[S(t)] = \mu \quad (8)$$

and

$$\lim_{t \rightarrow \infty} \mathbb{E}[S(t)^2] = \mu^2 + \frac{\sigma^2 \mu}{2\lambda} \quad (9)$$

Hence, μ the long-term mean, λ the rate at which the mean converges, and the noise coefficient σ affect the variance. It can be shown that for $S(0) \geq 0$, nonnegativity of $S(t)$ is preserved; that is, $S(t) \geq 0$ for all $t \geq 0$, with probability one. Further, the solution may attain the value zero if and only if $\sigma^2 > 2\lambda\mu$; see [9, Section 9.2] or [10, Section 7.1.5] for more details. Heston's stochastic volatility asset price model [11] takes the form

$$\begin{aligned} dX(t) &= \lambda_1 (\mu_1 - X(t)) dt \\ &+ \sigma_1 X(t) \sqrt{V(t)} dW_1(t) \end{aligned} \quad (10)$$

$$\begin{aligned} dV(t) &= \lambda_2 (\mu_2 - V(t)) dt \\ &+ \sigma_2 \sqrt{V(t)} dW_2(t) \end{aligned} \quad (11)$$

In this case, there are two components. The squared volatility $V(t)$ in equation (11) satisfies a mean-reverting square root process. For the asset price $X(t)$ in equation (10), the random quantity $\sqrt{V(t)}$ then takes on the volatility role that was played by the constant σ in equation (1), and the drift includes mean

reversion. In this model, the two Brownian motions $W_1(t)$ and $W_2(t)$ may be correlated.

Generally, if we move away from the simple linear SDE equation (1), then analytical solutions cease to be available and numerical simulations must be performed. Suppose we have a general Ito SDE

$$dY(t) = f(Y(t)) dt + g(Y(t)) dW(t) \quad (12)$$

where $Y(t)$ has m components, and the Brownian motion $W(t)$ has d independent components, so $f : \mathbb{R}^m \rightarrow \mathbb{R}^m$ and $g : \mathbb{R}^m \rightarrow \mathbb{R}^{m \times d}$, with $S(0) \in \mathbb{R}^m$ given. Then the Euler–Maruyama method computes approximations $Y_n \approx Y(t_n)$, with $t_n = n\Delta t$, of the form

$$Y_{n+1} = Y_n + f(Y_n)\Delta t + g(Y_n)\Delta W_n \quad (13)$$

where $\Delta W_n = W(t_{n+1}) - W(t_n)$ is the Brownian increment. In practice, each component of ΔW_n can be simulated by scaling a standard normal sample by $\sqrt{\Delta t}$; in MATLAB, this corresponds to `sqrtdt*randn`.

To illustrate the idea, Figure 2 shows an Euler–Maruyama approximation. Here we consider the linear SDE equation (1) with $\mu = 0.1$, $\sigma = 0.4$, and $S(0) = 1$, for $0 \leq t \leq 1$. The solid line shows the exact values of the solution (2) over a numerically generated Brownian path, at a spacing of 2^{-8} . (Discrete values have been joined in a piecewise linear fashion for clarity.) The asterisks show the values obtained by applying the Euler–Maruyama method (equation 13) with $\Delta t = 2^{-6}$. Here, the Brownian increments ΔW_n correspond to those for the exact

Figure 2 Exact SDE path (solid) and numerical approximation from Euler–Maruyama method (asterisks)

path. We see that Euler–Maruyama closely follows the exact path, but there is some visible error. At the final time $t = 1$, the discrepancy is 0.0359.

Traditional numerical analysis for timestepping methods regards the stepsize Δt as a small parameter and looks at the error in the numerical approximation in the limit $\Delta t \rightarrow 0$. In our context, at any time t the difference $Y(t_n) - Y_n$ between the exact and numerical solutions is a random variable, and consequently there are many, nonequivalent ways to measure the error.

One approach is to measure the “error of the means”, leading to so-called *weak convergence theory*. We say that a method has *weak order of convergence* equal to γ if there exists a constant C such that for all functions p in some class

$$|\mathbb{E}p(Y_n) - \mathbb{E}p(Y(\tau))| \leq C\Delta t^\gamma \quad (14)$$

at any fixed $\tau = n\Delta t \in [0, T]$ and Δt sufficiently small. (More precisely, the order γ is the largest such number.) Typically, the functions p allowed in equation (14) must satisfy smoothness and polynomial growth conditions. For appropriate functions f and g in equation (12), it can be shown that the Euler–Maruyama method (equation 13) has weak order of convergence $\gamma = 1$. In the case where $S(0)$ is nonrandom and $g \equiv 0$, the SDE collapses to a deterministic ordinary differential equation (ODE), whereby equation (13) becomes the Euler method, which is well known to be a first-order method in the classical ODE sense. This first-order accuracy, therefore, carries through to the SDE setting when weak convergence is considered.

By contrast, instead of the “error of the means” we could consider the “mean of the errors,” leading us into the realm of *strong convergence theory*. A method is said to have *strong order of convergence* equal to γ if there exists a constant C such that

$$\mathbb{E}|Y_n - Y(\tau)| \leq C\Delta t^\gamma \quad (15)$$

for any fixed $\tau = n\Delta t \in [0, T]$ and Δt sufficiently small. If f and g satisfy appropriate conditions, it can be shown that Euler–Maruyama has strong order of convergence $\gamma = \frac{1}{2}$. Note that this marks a departure from the deterministic setting – the presence of the stochastic term degrades the order from 1 to $\frac{1}{2}$.

It is natural to ask: which is more important, weak or strong convergence? The answer, of course, depends upon the context in which simulations are being performed. In many cases, the amount of interest is an expected value (for example, the discounted

average payoff of an option, under a risk-neutral measure), so that weak convergence is a natural concept. In other cases, it is of interest to observe particular solution paths, or to generate time series to test a filtering algorithm, making strong convergence highly relevant. The distinction has recently been blurred by the remarkable result in reference [12] that Monte Carlo estimation of SDE functionals can be made more efficient with a multilevel approach – computing solution paths over a range of Δt values, with different numbers of paths at each level. In this case, even though a weak (expected value) quantity is being computed, both the analysis and the resulting algorithm rely implicitly on the strong convergence properties of the numerical method.

Although the Euler–Maruyama method (equation 13) is still widely used, many methods with higher orders of weak and/or strong convergence have been derived. Generally, unless there is some special structure in the problem that can be exploited, achieving higher order is computationally expensive, and hence orders above 2 are very rarely used. Just as Taylor series form the basis for deriving and analyzing convergence properties of numerical methods for ODEs, the generalized concept of Ito–Taylor series forms the basis on which numerical methods for SDEs are studied. The text [2] covers the appropriate theory and gives many examples of methods. Other references in this area include [3], which deals with the state of the art in numerical SDE solving, and [13, 14] which give accessible, practical, introductions for those wishing to avoid measure theory and probability.

The SDE framework has been extended in various directions in attempts to describe real processes more accurately. For example, *jumps* [15, 16] are often introduced to account for abrupt, unpredictable “one-off” changes and, more generally, models can switch instantaneously between different SDEs to account for global changes in a physical process (for example, the market may lurch from confident to nervous, requiring a change in the volatility parameter). In many cases, it is straightforward to perform numerical simulations of these more sophisticated SDE-based models, although analyzing the approximation power of the numerical methods (e.g., proving convergence results) can be a lot more tricky [17].

Occupational Cohort Studies

Occupational cohort studies provide a powerful tool to investigate the risk of disease associated with a specified exposure. By a cohort, we mean a group of individuals that are followed over time for the purpose of identifying specific outcomes of interest. A cohort is prospective if the cohort is defined prior to the observed follow-up period and retrospective if the cohort is defined at a previous point in time, prior to the period of follow-up (*see Cohort Studies*). Since for many chronic diseases, an increased risk becomes apparent long after initial exposure, prospective cohorts are often impractical. For a retrospective cohort study, the follow-up period has already occurred and thus it only remains to determine previous exposures and identify health outcomes. Using the information on employment records, exposure can usually be estimated better in an occupational cohort than in the general population.

During the 1970s and 1980s, the retrospective cohort study became the gold standard for evaluating the relationship of exposure in occupational groups to chronic disease outcomes. Although estimates of exposure can usually be obtained from employment records, retrospective measures of disease are more difficult to obtain. Since measures of morbidity are often not maintained by employers and available information may vary in quality, a common measure of health outcome in a retrospective cohort study of an occupational group is mortality. The focus of this chapter will be on issues related to the design, conduct, analysis, and interpretation of retrospective occupational cohort studies where the primary outcome is cause-specific mortality.

Definition of the Cohort

In defining the cohort, we distinguish two types – a fixed cohort and a dynamic cohort. The fixed cohort selects all individuals who are working at a previous point in time. The cohort may be further restricted by requiring that individuals work in particular departments or plants, or that they work a minimum duration of time by the specified date. A dynamic cohort permits workers to enter over a

time interval. If the interval is large, the study may contain workers with considerably different hire dates and lengths of employment and thus will provide a more representative sample of the historical workforce. However, workers entering in the later years may contribute little information to the relationship of exposure and chronic disease, since they are usually younger (with lower baseline risk of chronic disease) and have less cumulative exposure. It is standard practice in a dynamic cohort to require a minimum duration of employment to be included in the cohort. Knowledge of the etiology of the disease of interest may influence the selection of the minimal duration of required employment. However, if very short durations of employment are used to determine eligibility, there may be a large increase in individuals who have insufficient exposure to elevate their risk of disease, thus unnecessarily increasing the resources necessary to complete the study. For many studies, a requirement of at least a 1-month or even a 1-year minimal employment seems to be reasonable.

Cohort Validation

The validation of a cohort is an important aspect of the conduct of an occupational mortality study. A retrospective cohort study depends on whether the available records are adequate to form the cohort and develop a job chronology for cohort members. Some plants periodically purge records because of space and cost considerations. Such purging is unlikely to be random, since employers often maintain files by category, i.e., active employees, retirees, and deaths. The records most likely to be purged are ones that are least likely to be needed and records of employees that died or terminated employment a long time ago are often targeted for elimination. Seniority lists, interviews with long-term employees, and aggressiveness in finding old records that may be in storage should all be explored. Examination of frequency distributions by year of hire, year of termination, duration of employment, time since first employment, and first letter of last name often identifies patterns that are consistent with missing records and can be used as a basis for further inquiry with the company or union. In a cohort study of aluminum reduction plant workers, the company had the work histories of cohort members available on microfilm [1]. However, when the microfilm was compared with a cohort constructed from seniority lists, it was estimated that 28%

of the records in one plant had not been microfilmed because of a processing error. The transition by many companies to computerized records does not eliminate the need for cohort validation, since errors may occur in the process of computerization of original hard copies. Furthermore, companies that have begun to computerize may still have earlier records that are not computerized or employees where only the more recent work histories have been computerized.

Vital Status and Cause of Death Determination

When conducting a mortality study, the vital status of cohort members must be determined at the specified date defining the end of the follow-up period. The initial information in regard to the vital status of the worker is usually the employer. Workers still actively employed or receiving pension benefits are assumed to be alive. If the employee died while employed or a death benefit was paid to survivors, the company may also have information on the date of death. Resolution of the vital status of the remainder of the cohort requires more effort. The available sources useful in determining vital status have varied over the years, in part as a reflection of confidentiality laws and their interpretation. Current sources useful for vital status determination include the Pension Benefit Information Company, Social Security Administration, Health Care Financing Administration, Motor Vehicles Bureaus, the National Death Index, and the Veterans Administration. Subjects whose dates of death are after 1979 can be sent to the National Death Index to obtain death certificate numbers, which can then be used to request the death certificates from the states. These sources vary in their ability to identify vital status, and several investigators have made comparisons among them [2–5]. The process of determining vital status can take considerable time and should be initiated early in the conduct of a study. Large percentages of individuals with missing vital status or unknown cause of death could introduce bias. Fortunately, with persistence, 95% vital status determination and 95% death certificates for known deaths is usually attainable.

After death certificates are obtained for individuals whose date of death occurred in the follow-up period, the cause of death should be coded by a qualified nosologist according to strict rules guided by

the International Classification of Disease (ICD). The rules are periodically changed, and long term studies may have different ICD revisions being in effect during the follow-up period. This can create a problem when conducting the analysis, since the definition of the disease is changing over time. Some investigators code the deaths certificates in the revision in which the death occurred, while others code them in a single revision and use comparability ratios to adjust the expected number of deaths for time intervals when other revisions were in effect. Comparability ratios are usually available in the transition year that a change in the coding occurs, and provide an estimate of the expected decrease or increase of death for selected disease categories owing to the change in ICD revision.

Exposure

The employment record containing the sequences and dates of jobs and departments provides some indication of exposure. Incorporation of this information into a format that can be used to test for a relationship of exposure can be a considerable data processing task. In a cohort of 23 326 aluminum reduction plant workers [1], there were 82 521 numerically distinct coded job categories in the 14 plants. One of the standard approaches is to transform these jobs into a job-exposure-matrix (JEM). Such a matrix provides an estimate of the average daily exposure for each job for specific plants and calendar time periods. Unfortunately, exposure measurements are not likely to be available for early time periods in many retrospective studies, and it may be necessary to extrapolate from exposure measurements in the present time period, taking into consideration general plant records and changes in technology. In a large cohort of synthetic vitreous fiber production workers, Smith *et al.* [6] describe five steps in the construction of the exposure matrix for each plant: (a) development of a technical history of operations including periods of stability, points of change in exposure, and potential confounding exposures, (b) development of a department-job dictionary, (c) collection of company exposure measurements and development of quantitative measures, (d) integration of estimates with the technical history to produce exposure extrapolation tables, and (e) development of an exposure matrix for each plant. The final step is to link average exposures with

the job and department for plant and calendar time, and use this in the analysis. Preferably, quantitative estimates of exposure can be made, but for some cohorts it may only be possible to classify into categories (e.g., exposed *versus* not exposed or none, low, medium, and high). Typical summary measures of exposure include time since first exposure, cumulative exposure, average intensity of exposure, and length of time in a high exposure category. Although analysis based on a primary exposure index is preferred, it is still useful to supplement exposure analysis with analysis based on length of employment in jobs and/or departments considered exposed or highly exposed. There has been much discussion of the accuracy of the JEM approach in estimating true exposure (e.g. [7–9]). Some of the concern relates to the variability of exposures of individuals with the same job title. This variability is probably higher in population-based studies that apply the JEM to a range of industries (e.g. [10, 11]) than in studies where the JEM is constructed separately for each plant. An alternative to the JEM is to have a panel of experts construct work histories for individuals [12]. There continues to be discussion of the relative merits of the two approaches. Recent examples of the application of the JEM approach to occupational cohorts include its use in the textile industry in Shanghai, China [13], and its use in a US cohort of 15 plants producing synthetic vitreous fibers [6].

Another criticism of retrospective methods of constructing exposure is the potential error resulting from extrapolation to time periods for which there are no exposure measurements. This is always a legitimate concern, but there is no totally satisfactory way to circumvent the uncertainty of such extrapolation. The investigator should do as much validation as possible. Although no direct measurements may exist for some jobs at early time periods, sometimes, indirect measures can be used in the extrapolation. These include airborne measurements taken during the same time period at other plants with similar processes, urinary measurements that are correlated with airborne concentrations, and measurements available on other exposures that are known to be correlated with the exposure of interest.

Mortality Indices

A variety of summary indices have been used in occupational mortality studies [14, 15]. The most

common, the standardized mortality ratio (SMR), is defined as the ratio of the observed to the expected number of deaths where the expected number of deaths is determined from a standard population. Usually, but not always, it is the convention to multiply the ratio by 100. Typically, the SMR will be adjusted for age, gender, race, and calendar time, and the standard comparison is countrywide or regional cause-specific death rates.

The SMR for the i th cause of death is given by

$$SMR_i = \frac{\sum_j d_{ij}}{\sum_j D_{ij} p/P} \times 100 \quad (1)$$

where d_{ij} is the observed number of deaths from cause i in stratum j , p is the person-years at risk in the occupational group, D_{ij} is the number of deaths from cause i in stratum j in the standard population, and P is the person-years at risk in the standard population.

A person-year is defined as the equivalent of one individual's experience for 1 year. The total person-years at risk is obtained by summing the years an individual is at risk of death, over all individuals in the study. Figure 1 shows six individuals in a dynamic cohort and their corresponding person-years at risk. The cohort definition required at least 1 year employment between January 1, 1980 and December 31, 1994, and follow-up is continued through December 31, 2000. Assuming that the estimate of the expected value is based on a large population, the observed number of deaths can be assumed to be a Poisson distribution with known parameter. We can then place confidence intervals on the SMR, using the method given in Bailor and Ederer [16]. Despite its widespread use, there are theoretical and practical limitations of the SMR. When considering the usefulness of an index in comparing the mortality patterns of two populations, Silcock [17] proposes the following two desirable properties:

1. If the ratio of all the age-specific rates for the two populations is in the interval $[a, b]$ then the ratio of the overall indices for the two populations is in $[a, b]$.
2. If the overall indices of the two populations differ then the inequality should be because of the fact that some of the age-specific rates are unequal in the two populations.

Figure 1 Person-years at risk for members of a hypothetical cohort. T: terminated employment, D: deceased, A: alive at last contact, and TL: terminated employment and no follow-up information

Silcock demonstrates the SMR has neither of these properties. Subsequent investigators have highlighted these and additional limitations of the SMR as a mortality index (e.g. [15, 18]). Although, in general, the SMR lacks some desirable mathematical properties, under certain assumptions, it is an appropriate index for comparing different exposure groups.

Gail [19] notes that if we assume the observed deaths obey a Poisson distribution indexed by age strata and population (e.g., exposure group), then the SMRs among several populations can be compared using a multiplicative model. Tests of hypothesis of equality of the SMRs can be conducted as long as there is no interaction with age. Gail provides a formal test for interaction as well as a test for equality of SMRs across populations, assuming no interaction exists. Although the same test can be conducted in the context of a regression model, Gail's approach is formulated in terms of simple χ^2 statistics and is conceptually more readily interpretable, particularly for nonstatisticians.

A decision that must be made when using a SMR is the selection of the control group. For cohorts in the United States, the most common external control group is the total US population but others can be used, including county and state populations. Arena *et al.* [20] compare the SMRs for selected causes of death for 31 000 nickel workers, using the total US population as a control group to the SMRs obtained when the local population was the control. Although mortality patterns were similar, the SMRs

tended to be lower when local population rates were used. In the conduct of the aluminum reduction plant workers study, only one of the Soderberg plants had a statistically significantly elevated SMR for lung cancer. However, this plant was located in a region known to have high rates of lung cancer. When comparisons were made with local county rates the SMR decreased from 146 to 83 and was no longer statistically significant. In general, although for most of the studies, county, state, and US rates lead to the same conclusions, there are exceptions, and possible dependence of the results on the choice of the standard population should always be considered.

The selection of the appropriate control is a difficult one in epidemiological studies, since it can result in both known and unknown sources of bias. One particular bias that has been given considerable attention in occupational cohort studies using an external control group is the healthy worker effect. The healthy worker effect is the terminology referring to a particular type of confounding that results because we are comparing a group of "healthier" workers to a general population that may include people too unhealthy to work [21–23]. Regardless of the reasons, it is frequently observed that occupational cohorts have all-cause SMRs less than 100 when compared with general populations. Unfortunately, a variety of factors affect the healthy worker effect, including age, length of follow-up, race, and specific cause of death. Methods of addressing the healthy worker effect include selection of an internal control

and testing of a dose–response relationship. This type of selection bias tends to attenuate in cohorts with longer follow-up and appears stronger for categories of cardiovascular disease than cancer. It is also possible that selection bias can occur after the workers enter the cohort, if they select themselves into job categories with less exposure or selectively terminate employment [24]. The term healthy worker survivor effect is used to describe a selection of workers from the exposed jobs of interest as a result of events occurring after initial employment. Arrighi and Hertz-Picciotto [25] provide an overview of the healthy worker survivor effect and suggest several approaches to control it. Robins [26–28] suggests some more analytically sophisticated methods of addressing this type of selection bias.

Another disadvantage of the SMR is that except for potential confounders such as age, race, gender, and calendar time, one cannot easily adjust for other potential confounding variables. Variables such as date of hire, birthplace, smoking history, and employment history at nonstudy plants are all variables that may be related to risk and confound the relationship of the exposure of interest to the cause-specific disease. Unfortunately, cause-specific death rates for general populations are not usually available for strata based on these other potential confounders, so they cannot be incorporated into the computation of an SMR. These variables are more readily controlled within the framework of a regression model.

Example 1 Rockette and Arena [1] investigated the mortality patterns of workers with five or more years of employment in 14 aluminum reduction plants. The investigation used data collected in a previous study by other investigators, so the completeness of the cohort was verified using company seniority lists. Two plants were identified as having an unacceptable number of missing records that could not be obtained (6 and 16%, respectively). This resulted in one plant being excluded from some of the analysis. The final cohort consisted of 21 829 members. Follow-up for vital status was conducted using lists of active employees and pensioners, the Social Security Administration, State Motor Vehicle Bureaus, and telephone follow-up. A complete vital status determination was made on 98.8% of the cohort, and death certificates were obtained on 97.6% of those presumed to be dead. Determination of the primary cause of death was done by a nosologist, according to the

seventh revision of the International Classification of Disease (ICDA). SMRs adjusted for age, race, and calendar year were used to compare cause-specific mortality of reduction plant workers to the total US male population. Since the follow-up period covered several ICDA revisions, comparability ratios were used to convert rates that were equivalent to the seventh revision. As expected, the “all causes” SMR was significantly low for both whites ($SMR = 88.0$) and nonwhites ($SMR = 73.2$), suggesting the presence of a healthy worker effect. Significantly elevated SMRs were found in selected working subgroups, for pancreatic cancer, lymphohematopoietic cancers, genitourinary cancers, and nonmalignant respiratory disease. SMRs were compared for different exposure groups after testing to determine if the assumptions of a multiplicative model were violated. There was a significant increasing risk from pancreatic cancer with increasing length of employment in the pot-rooms ($p < 0.01$).

Other Mortality Indices

Other indices have been used in occupational mortality studies. The comparative mortality figure (CMF) (sometimes referred to as the *standardized rate ratio*) meets both of Silcock’s requirements for a mortality index. The CMF is a method of direct adjustment where the observed deaths in the cohort are compared to an expected value obtained by applying the observed age-specific death rates in the cohort to a population with a standard age distribution. Although the CMF has more desirable analytical properties than the SMR, the estimated mortality rates tend to be highly variable for most causes of death because of the low frequency of occurrence. It is seldom used in occupational cohort studies.

Sometimes, there is no well-defined cohort, or the resources are not available to conduct a cohort study. In these situations, one can conduct a proportionate mortality study using deaths known to the employer. The proportionate mortality ratio (PMR) is used as the summary index. Steenland and Beaumont [29] used a PMR study to investigate cause-specific mortality in members of the Granite Cutters Union. Deaths were identified from union death benefit records and a statistically significant PMR of 418 was obtained for nonmalignant respiratory disease. Checkoway *et al.* [30] have noted that PMR studies

are closely related to a special type of case–control study.

The PMR compares the proportion of deaths from a specific cause to the proportion of expected deaths in a standard population. Similar to an SMR, it is summed over strata that are typically defined by age, gender, race, and calendar time. The formula for the PMR is equivalent to the formula for an SMR where the person-years at risk have been replaced by total deaths. Specifically,

$$PMR_i = \frac{\sum_j d_{ij}}{\sum_j D_{ij}d/D} \times 100 = \frac{\sum_j d_{ij}/d}{\sum_j D_{ij}/D} \times 100 \quad (2)$$

where d_{ij} is the observed number of deaths from cause i in stratum j , d is the total number of observed deaths, D_{ij} is the number of deaths from cause i in stratum j in the standard population, and D is the total number of deaths in stratum j in the standard population.

A serious limitation of proportionate mortality studies is the failure to include many of the deaths that occurred after the worker terminated employment. A second limitation is due to an undesirable property of the PMR index. Specifically, if there is a deficit in one cause of death there is correspondingly an increase in other categories. This characteristic of the PMR has been called the *see-saw effect* [31].

The PMR can be approximated by the ratio of the cause-specific SMR and the SMR for all causes [31–34]. Since the healthy worker effect usually results in an all causes SMR less than 100, and since the healthy worker effect is usually stronger for cardiovascular disease, there is a tendency for the PMR to be elevated for malignancies. This tendency for an elevated PMR for cancers is made worse by the practice of testing multiple hypothesis in the cancer category. Rockette and Arena [35] show in a simulation study that the probability of at least one falsely elevated PMR in 24 cancer categories was 0.89, if there is a healthy worker effect of 15% in all cardiovascular diseases. This was due both to multiple comparisons and the see-saw effect. In contrast, the probability of a falsely elevated SMR in a malignancy category was 0.36, and was not affected by a healthy worker effect in cardiovascular disease.

Because of these limitations, the PMR is usually used only as a screening tool to determine if there is a need for further investigation rather than a method to obtain an estimate of risk. If there is a well-defined cohort, there is no need to use a PMR instead of an SMR.

Regression Models

Although SMR analyses have historically comprised a large part of the analysis done in retrospective cohort studies, use of regression models provide several advantages. Specifically, regression analysis permits incorporation of continuous as well as discrete variables, can readily incorporate confounding variables, and can be used to test for interaction (i.e., effect modification). Although often used in studies with internal controls, they can also be formulated in a manner that can be viewed as a generalization of an SMR analysis.

Proportional Hazards Model

A cohort study can be viewed as time to event analysis where we are concerned with relating a time-dependent exposure variable to the time at which a death occurs for a specific cause. A commonly used model to investigate “time until response” variables is the proportional hazards model [36]. The proportional hazards model assumes that

$$\ln \frac{\lambda(t; \vec{x})}{\lambda_0(t; \vec{x})} = \vec{\beta} \vec{x} \quad (3)$$

where t denotes time, $\vec{x}$ denotes a vector of covariates, $\lambda_0(t; \vec{x})$ is the baseline hazard function, and $\lambda(t; \vec{x})$ is the hazard function for a given vector of covariates.

The hazard function gives the conditional failure rate which we define to be the limit of the probability (as $\Delta t \rightarrow 0$) that an individual has an event in the small interval $(t, t + \Delta t)$ given that the individual has survived to time t .

The covariate vector $\vec{x}$ may contain components that relate to exposure as well as potential confounders. For cumulative exposure, a lag time is sometimes used, since recent exposures are unlikely

to cause chronic disease. Gilbert [37] used the proportional hazards model to investigate the relationship of radiation exposure to mortality from myeloid leukemia. Instead of treating confounding variables as covariates, Gilbert treats them as stratification variables, and cumulative exposure becomes the only covariate. This approach results in a more robust model, since the covariates are not required to satisfy the proportionality assumption.

Assuming only one covariate x (cumulative exposure), the derivative of the log likelihood function with respect to β is given by

$$L'(\beta) = \sum_{i=1}^n x_i(t_i) - \frac{\sum_{k \text{ in } R_i} x_k(t_i) e^{\beta x_k(t_i)}}{\sum_{k \text{ in } R_i} e^{\beta x_k(t_i)}} \quad (4)$$

where i indexes the deaths due to a particular cause, t_i is the calendar year of death for worker i , R_i denotes the risk set of workers at time t_i , and $x_k(t_i)$ is the cumulative exposure for the k th worker at time t_i . The risk set at time t_i is the set of workers who are alive and can have an event at time t_i . If confounding variables are addressed using stratification, then the risk set (R_i) is restricted to workers having the same set of confounding variables as the worker with a death at time t_i . Standard numerical techniques can be used to solve the equation $L'(\beta) = 0$ to obtain the maximum-likelihood estimate. Statistical packages such as SAS provide several methods to test the hypothesis $H_0 : \beta = 0$, including the likelihood-ratio test, Wald's statistic, and the score statistic. The score statistic provides a particularly intuitive answer. Asymptotically, each $x_i(t)$ is normally distributed with mean μ_i (estimated by the average exposure of members of R_i) and variance σ_i^2 (estimated by the variance of the exposure measurements of members of R_i). In estimating the variance, we use in the denominator the number of individuals in R_i . The test statistic

$$Z = \frac{\left(\sum_{i=1}^n x_i(t_i) - \sum_{i=1}^n \mu_i \right)}{\left[\sum_{i=1}^n \sigma_i^2 \right]^{1/2}} \quad (5)$$

is asymptotically $N(0,1)$. Thus, at each point where a death occurs, we are comparing the cumulative

exposure of the individual with a death at time t_i to the average cumulative exposure of individuals in the risk set.

Breslow *et al.* [38] propose a regression model that can also incorporate external rates. Let $\lambda_i^*(t)$ be the rate for the i th individual in the t th year and assume the relationship

$$\ln \frac{\lambda_i(t)}{\lambda_i^*(t)} = \beta x \quad (6)$$

where x_i is a vector of covariates (i.e., exposure variables and potential confounding variables) and $\lambda_i^*(t)$ is a rate determined by age and the calendar time period. This model is similar to the Cox proportional hazards model except that $\lambda_i^*(t)$ are known rates for the general population. For the special case where there is a single covariate with $x_i(t) = 1$, the maximum-likelihood estimate of β is the total observed deaths divided by the expected deaths. The expected deaths are obtained by applying the external rates to each individual's person-years. Thus, this approach provides a generalization to the regression setting of standard SMR analysis.

Breslow *et al.* [38] also suggest using age as the time variable rather than calendar time. This adjusts for age more precisely than if it were a stratification variable, and it also attenuates some of the problems that can occur if cumulative exposure and time on study are too highly correlated. When age is considered to be the primary time variable, the number of individuals in successive risk sets does not necessarily decrease over time.

Poisson Regression

Poisson regression models the number of deaths occurring in different strata (defined by demographic variables and exposure). They are particularly useful in accommodating grouped data. A summary of Poisson regression models can be found in Breslow and Day [39]. Following their notation, we let

d_{jk} be the observed deaths in the j th age-group and k th exposure group, n_{jk} be the person-years in the j th age-group and k th exposure group, and λ_{jk} be the unknown mortality rate in the j th age-group and k th exposure group.

We assume the d_{jk} are independent Poisson variables with corresponding $E(d_{jk}) = V(d_{jk}) = \lambda_{jk} n_{jk}$.

Assuming a multiplicative model, we obtain

$$\ln \lambda_{jk} = \alpha_j + \beta_k \quad (7)$$

where α_j is the effect associated with the j th age-group ($\alpha_j = \lambda_{j1}$) and β_k is the effect associated with the k th exposure group ($\beta_1 = 0$). Additional variables may be added to the model to incorporate the effect of potential confounders, or product terms can be included to test for effect modification. There is also an additive form of the Poisson regression model that sometimes provides a better fit of the data, but for some data sets may result in convergence problems when iteratively estimating the parameters.

Within the framework of existing software, the Poisson regression model is often easier to implement than the proportional hazards model if there are time-dependent covariates (e.g., exposure). This is because the time-varying aspects of the problem for Poisson regression are incorporated in the computations of person-years.

Hybrid Analysis

Initially, occupational cohort studies were seen as an alternative to case-control studies or PMR studies. Case-control studies are true retrospective studies in that they start with a group having the cause-specific death of interest and an appropriately selected control group, and then compare the previous exposures in the two groups. Case-control studies are subject to more biases than cohort studies some of which relate to the methods of selection of the cases and controls. Also, since a well-defined population of individuals who can have an event is not required, estimates of risk for the individual groups cannot be obtained.

However, an advantage of a case-control study is that it requires less resources than a cohort study and takes less time to complete. In addition, information can be obtained on potential confounders that are not feasible for a large cohort. An important improvement in the design of cohort studies was the incorporation of a case-control study within the cohort, resulting in a study with some of the advantages of each approach. Such a study does not have the same potential for bias in selecting cases and controls that are associated with a classical case-control study, and in addition, direct estimates of risk can be obtained. However, unlike a standard cohort study, adjustment can be made for additional confounders

by obtaining more detailed information on the set of cases and a sample of controls.

Furthermore, since primary outcomes of interest in occupational cohorts often include smoking related cancers (e.g., lung cancer) that could confound the relationship of exposure and disease, incorporating a case-control study within the framework of the cohort is considered by many to be an important aspect of the investigation of mortality patterns of occupational groups.

Nested Case-Control Studies

The concept of a nested case-control study appeared to have been first proposed by Mantel [40], and first applied in an occupational setting by Liddell *et al.* [41] to investigate lung cancer risk in a cohort of asbestos workers. In such a study, a historical prospective study is conducted in the manner previously described. Once the follow-up is completed, the deaths are identified for the cause of interest. A random sample of the controls is selected from the risk set for each case. Often controls are required to have similar birth years, race, and gender. In addition, controls are required to have obtained the same age as the case. When tabulating exposure for the controls, one considers only the exposures acquired up to the time of death of the case. There are additional constraints that are sometimes placed on the selection process. Sometimes, a case is not allowed to serve as its own control, or deaths from other causes that may be related to exposure are excluded. However, it is generally agreed that to avoid bias, controls can include individuals that later become a case [42, 43].

In summary, a nested case-control study has all of the advantages of a historical cohort study and, in addition, permits more detailed information to be collected on potential confounders on the disease cases and a set of randomly selected controls. Thus, the design is superior to conducting a standard cohort study, since it is now feasible (because of the smaller sample size) to obtain more detailed exposure information and/or information on other factors (i.e., smoking, diet, etc.), using interviews and questionnaires.

Case-Cohort Study

An alternative design, which also samples from a cohort study, is the case-cohort design [44]. The

overall concept is the same as the nested case-control study, except that random samples are obtained from the cohort, independent of the health outcome status of the cohort member. Armstrong *et al.* [45] use a case-cohort design to investigate the cancer mortality in a cohort of aluminum reduction plant workers. An advantage of the case-cohort design is that one does not need to wait for the completion of follow-up before starting to obtain the more detailed information required in the case-control component of the study. Various statistical issues that facilitate the proper application of nested case-control studies and case-cohort studies have been addressed in the literature (e.g. [46–49]). These include sample-size estimation, appropriate methods of sampling, utilization of matching, and a comparison of the relative advantages of the two designs.

Example 2 Marsh *et al.* [50] investigated the mortality experience of 32 110 workers employed for at least 1 year from 1945 to 1978 at any of 10 US fiberglass plants. After determining vital status and obtaining death certificates, cause-specific mortality was investigated by computing SMRs using US and local county rates as the control group. Since a primary outcome of interest in the cohort was respiratory system cancer (RSC), a nested matched case-control study was conducted, which enabled the investigators to adjust for the potential confounding effects of smoking. Cases were defined as all male members who died from RSC during 1970–1992, and for each case, one control was randomly selected from all male members at risk at the same age as the corresponding worker who died. Controls were also matched to cases by date of birth (within 1 month), but to avoid overmatching on exposure, controls were not matched with regard to plant. Smoking histories were obtained through structured telephone interviews with the respondent (some controls were alive) or a knowledgeable informant such as a surviving family member. Interviews were completed for 88.3% of the 716 cases, and 80.2% of the 713 controls. Estimated risk ratios were obtained by applying conditional logistic regression to the matched case-control sets. Workers in areas with fiber exposure had a RR of 1.79 ($p = 0.17$) and after adjustment for smoking, this decreased to 1.37 ($p = 0.50$). Investigation of duration of fiber exposure, cumulative exposure, and average intensity of exposure revealed no pattern of increasing risk for RSC mortality for any of the three

exposure measures with or without adjustment for smoking.

Summary

Retrospective cohort studies in occupational groups provide a powerful tool to identify relationships of exposure to chronic diseases. The studies require the existence of historical employment records and usually use cause-specific mortality as the primary outcome. The conduct of these studies requires considerable effort both in obtaining estimates of exposure and in ascertaining the vital status and cause of death of the large number of individuals that typically comprise the cohort. Methods of analysis continue to improve. Earlier analyses relied mostly on the SMR as a summary statistic. Interpretation of the findings of these studies were hampered by limitations of the index, a particular type of bias known as *the healthy worker effect*, and the difficulty of incorporating potential confounders that are not considered in standard population death rates. The development of appropriate regression models has addressed many of the limitations of these early analyses. Furthermore, the importance of evaluating the effect of potential confounders often results in nested case-control studies or case-cohort studies being included as part of the analysis.

Occupational Risks

Risk is the probability of an adverse event occurring [1]. Occupational risk, specifically, deals with the probability of injury or illness occurring as a result of hazards within the workplace. In general, there are six types of occupational hazards: safety, chemical, biological, physical, ergonomic, and psychosocial (Table 1) [2]. Some examples of safety hazards include the operation of moving parts or vehicles, functioning in slippery or entangled conditions, or working with explosive materials. In contrast, chemical health hazards include exposures to dusts or fibers (e.g., silica or asbestos), solvents (e.g., benzene or trichloroethylene – see **Benzene**), heavy metals (e.g., lead or mercury), and pesticides (e.g., organochlorines or organophosphates). Biological hazards involve the exposure to pathogens that may be present in the workplace such as human immunodeficiency virus (HIV), hepatitis B, tubercle bacillus, and legionella. Physical hazards that may be encountered in occupational settings include radiation, noise, heat, and temperature. Repetitive motion, awkward posture, or lifting are all examples of ergonomic hazards that can occur in the workplace. Lastly, psychosocial hazards are hazards that can negatively affect the mental health of workers. Unusual or inconsistent shift work can fall into this class of hazards [3]. Table 1 provides examples of hazards that fall within each of these hazard categories along with an example of a potential corresponding adverse health effect.

Industrial hygienists and safety professionals are trained to recognize, evaluate, and control these workplace hazards to ultimately prevent injury and illness. Occupational health practitioners, such as physicians or nurses who specialize in occupational medicine, are trained to recognize the hazards in a patient's workplace that may have resulted in his/her medical diagnosis. Together, these professionals help reduce the probability of the occurrence of workplace illness and injury.

History of Occupational Health

The management and control of occupational risks has a rich history. Occupational risks were first noted in mid-sixteenth-century texts such as Georgius Agricola's, *De Re Metallica (On the Nature of Metals)*.

Bernardino Ramazzini published a text 150 years later, solely devoted to occupational health entitled, *De Morbis Artificum Diatriba (Diseases of Workers)*. Although occupational health has been recognized for centuries, much of modern day state and federal legislation regarding workplace safety and health was brought about in response to several unfortunate events [4]. For example, public awareness of occupational risks in the U.S. peaked after two major events occurred in the twentieth century, the Triangle Shirtwaist Fire and the Hawks Nest Incident (discussed below).

In 1911, a 10-story building in New York City caught fire and killed 146 young women of the Triangle Shirtwaist Company. Overcrowded and poorly supervised working conditions, locked exit doors, inadequate fire exits, and a lack of sprinklers were to blame for the deaths of the garment workers, many of whom died while trying to escape by jumping from the ninth floor windows [5]. This fire helped pave the way to more comprehensive legislation to regulate occupational risk both at the state and federal level. In fact, by 1920, almost all states had some form of limited workplace safety law in place [6]. Furthermore, 2 years after the fire, the US Department of Labor was created to address the protection of the rapidly growing labor force in the United States.

One of the first true tests of the Labor Department was dealing with the Hawk's Nest Incident, beginning around 1930. This project involved the construction of the Hawk's Nest Tunnel near Gauley Bridge, West Virginia as part of a hydroelectric project. The exact death toll is not known, but most accounts report that approximately 500 workers died and over 1500 workers became ill due to silica exposure [7, 8]. Broadcast as front page news and carried in such widely read news journals as *Time*, *Newsweek*, *The Nation*, and *Science*, the Gauley Bridge story, containing details regarding the hazards of silica dust exposures and appropriate methods of protection [9], spread to millions of Americans. Both the Triangle Shirtwaist Fire and the Hawk's Nest Incident created immediate public outrage. As a result, safety inspectors were hired, and many other serious safety and health problems confronting workers were soon identified.

As public awareness and concern over occupational risk continued to grow, the U.S. Congress began to give federal workplace safety and health legislation serious consideration, especially in the late 1960s. At the time, it was estimated that 14 000

Table 1 General examples of occupational hazards and potential adverse effects by type of occupational risk

Risk	Hazard	Potential adverse effect
Safety	Sharp equipment	Lacerations
	Moving machinery	Amputations
	Wet or icy environment	Slips
	Manifolds	Entanglement
	Scaffolding	Falls
	Reactive materials	Explosions
Chemical	Flammable materials	Fires
	Inhalation of excess dusts	Organ damage
	Enzyme exposure	Sensitization
	Inhalation of friable asbestos fibers	Cancer
	Pesticide exposure	Acute response
Biological	Dermal exposure to solvents	Dermatitis
	Needles	HIV
	Mold	Legionella
	Working around or with an infected population	Tubercle bacillus
Physical	Contact with bodily fluids	Hepatitis B
	Ionizing radiation	Cancer
	Noise	Hearing loss
Ergonomic	Repetitive motion	Carpel tunnel syndrome
	Awkward posture	Backaches
	Heavy lifting	Muscle strain
	Hot tools	Skin burns
Psychosocial	Rotating work shifts	Fatigue
	Hostile or harassing environment	Stress

workers died annually from work-related accidents and the financial losses from work-related deaths and accidents were estimated at \$1.5 billion in wages and \$8 billion in the gross national product, annually [10]. On December 29, 1970, President Richard Nixon signed into law the Occupational Safety and Health (OSH) Act, creating the Occupational Safety and Health Administration (OSHA), a regulatory agency, and the National Institute for Occupational Safety and Health (NIOSH), a research institute. The purpose of the act was “to assure so far as possible every working man and woman in the nation safe and healthful working conditions and to preserve our human resources” [11]. The passage of the OSH Act in 1970 was the single most important event in American history for workplace safety and health.

Regulating Occupational Risk

Under the OSH Act, part of OSHA’s responsibility is to regulate occupational risk. OSHA does this

by writing both recommendations and enforceable policies and procedures designed to limit and control occupational hazards. For example, it is against OSHA regulation to allow workers to perform jobs on work surfaces over 6 ft high without having guard rails, a safety net, or a personal fall arrest system in place [12]. The purpose of this regulation is to reduce the risk of worker injury or fatality from falling. Table 2 presents additional examples as to how OSHA works to regulate occupational risks.

OSHA also regulates occupational risk by setting occupational exposure limits (OELs) that they call permissible exposure limits (PELs). PELs represent maximum acceptable exposure levels an employee may be exposed to without incurring a significant risk of adverse health effects. The American Conference of Governmental Industrial Hygienists (ACGIH), a society consisting of mostly governmental and academic industrial hygienists, was the first professional organization to establish OELs in the United States. In 1941, the Threshold Limit Values for Substances

Table 2 Examples of how OSHA regulates different types of occupational risk

Occupational risk	Hazard	OSHA guideline/regulation
Safety	Flammable liquids	29 CFR 1910.106 “Flammable and combustible liquids”
Chemical	Benzene	29 CFR 1910.1028 “Benzene”
Biological	Bloodborne pathogens	29 CFR 1910.1030 “Bloodborne pathogens”
Physical	Noise	29 CFR 1910.95 “Occupational noise exposure” Guidelines such as “Ergonomics for the prevention of musculoskeletal disorders”
Ergonomic	Repetitive motion	Guidelines for “Retail grocery stores”

Committee of ACGIH was formed and charged with investigating, recommending, and annually reviewing OELs for chemicals in the workplace. In 1946, the committee adopted 148 OELs and referred to them as *maximum allowable concentrations*. These were later termed *threshold limit values* (TLVs), and the first publication of the documentation or evidence used to establish the TLVs was made available in 1962 [13]. A similar committee, the MAK Commission, was established in Germany in 1955, which also began publishing recommended OELs [14].

Many OELs and work practices designed to reduce occupational risks were adopted by state and federal governments. For example, by 1954, 19 states had incorporated the TLVs into their state health and safety programs [15, 16]. In addition, the US Department of Labor adopted the 1950 ACGIH TLVs as maximum exposure limits when they published the Safety and Health Standards for Contractors performing federal supply contracts under the Walsh–Healy Public Contracts Act, in 1952 [17]. Furthermore, under Section 6 (a) of the OSH Act, the Secretary of Labor was permitted to promulgate any national consensus standard or established federal standard as an occupational safety or health standard over a 2-year period if it resulted in improved safety or health. As such, OSHA adopted the safety and health standards under the Walsh–Healy Act that included the 1968 ACGIH list of TLVs. The TLVs became enforceable by law as OSHA PELs [18].

OSHA has promulgated many different types of PELs for numerous chemicals and physical agents present in the workplace. The most common PEL is an 8-h time weighted average (TWA) (8-h TWA), which represents a maximum exposure level averaged

over an 8-h work day to which workers may be repeatedly exposed assuming 40 h workweeks. For example, the 8-h TWA OSHA PEL for trichloroethylene is 100 ppm. OSHA also has PELs designed to protect against acute exposures. For these exposures, OSHA has promulgated a short-term exposure level (STEL) that identifies a maximum exposure level that should not be exceeded in a 15-min time period. An example of this is the benzene 5 ppm STEL. Furthermore, OSHA sometimes sets ceiling values that represent values that should not be exceeded under any circumstance. In the case of chlorine gas exposure, OSHA promulgated a ceiling level of 1 ppm.

Cancer Risk

In a landmark article, *Determining an Acceptable Level of Risk* by Travis and Hatemer-Frey [19], they identified that 70% of chemical carcinogens had a postregulatory added lifetime estimated risk greater than 1×10^{-6} and the other 30% had a postregulatory added lifetime estimated risk greater than 1×10^{-4} . From this, it was revealed that among regulated chemicals, some risks in the range of 1×10^{-6} to 1×10^{-3} were acceptable [19].

OSHA PELs are designed to minimize the risk of all types of adverse health effects that may be caused by occupational exposure. However, one of the most sensitive health endpoints that PELs regulate against is cancer. Allowable exposure to carcinogenic hazards varies from chemical to chemical [20]. Although OSHA has used actual data of work-related deaths as benchmarks to develop occupational acceptable risk levels, OSHA has not generally regulated below 1×10^{-3} for occupational carcinogens owing

to technical feasibility. The OSHA PELs regulate workplace hazards to a level where the risk is not necessarily insignificant, but to where the risk is considered “acceptable” in a workplace environment [21].

OSHA has, *de facto*, identified a level of acceptable risk associated with the workplace by defining “safe” as not the equivalent of risk-free, because in some work environments the activities may or may not involve some level of minimal risk [22]. Furthermore, some research has shown that workers are presumed to be willing to accept higher levels of risk, especially when there are significant gains such as salary or benefits [23, 24]. The Supreme Court decision, *Industrial Union Department, AFL-CIO v. American Petroleum Institute et al.* 448 U.S. 607 [1980] suggested that significant occupational risk be determined by comparing the risk in question with other common occupational risks. It was also determined by the Court that an occupational lifetime cancer risk of 1×10^{-3} is significant and, therefore, this decision was extremely influential in defining the acceptable occupation risk for OSHA [22].

Unlike occupational risks, where, as mentioned previously, the level of risk is considered in exchange for some beneficial gain to the worker, environmental exposures and hazards have been regulated U.S. by the US Environmental Protection Agency (EPA) to generally control theoretical risks to between 1×10^{-4} (*de manifestis*) and 1×10^{-6} (*de minimis*) [22]. While occupational and environmental risks have been regulated differently (that is, have different target risk criteria), OSHA has recognized that if the technology was available, certain workplace hazards should be regulated below 1×10^{-3} . Quite similarly, EPA has repeatedly rejected the notion that it can establish a universal, “brightline” acceptable risk that should never be exceeded under any circumstances [22].

Controlling Occupational Risks

To comply with OSHA regulations designed to minimize occupational risks, occupational health professionals, such as industrial hygienists must recommend the implementation of various control measures. The three types of controls utilized, listed in order of effectiveness and often referred to as the *hierarchy of controls* are: engineering, administrative, and personal protection, as illustrated in Table 3. In practice, occupational risks are often minimized using a combination of the three approaches.

Engineering controls are considered the best method of control and should be implemented first because they include methods that systematically eliminate or minimize the degree of exposure. These controls often involve changing the industrial process. For example, eliminating the use of the hazardous material or substituting the material with a less hazardous one are ideal engineering controls. Enclosing a hazardous process so that a worker does not have the potential to be exposed, and the use of local exhaust ventilation are other engineering controls measures. If implementing engineering controls is not technologically or economically feasible, an occupational health professional may have to rely on administrative controls; often considered the second best method.

Administrative controls usually involve a change in procedures. Reducing the time a worker is required to work with or around a hazardous substance or limiting the quantity of hazardous material a worker is required to use are examples of administrative controls. Another example is when one establishes procedures that dictate where and how a worker must sit or stand in his/her work area, in relation to the hazardous material.

Personal protective equipment (PPE) is the third control measure; and it should be used as the technique of last resort only when the implementation

Table 3 Examples of occupational risk controls

Engineering	Administrative	Personal protection
Process elimination	Job placement	Respirators
Material substitution	Worker rotation	Ear muff/plugs
Process automation	Job timing	Gloves/barrier creams
Process isolation	Change in housekeeping procedures	Protective clothing
Enclosure of process	Change in maintenance procedures	Immunizations

of engineering and administrative controls fails to meet minimum standards designed to protect workers. Personal protection in the form of such items as respirators, hard hats, safety shoes, and gloves, etc. can be very effective, although their use may often pose some incremental risk to the worker. Although there is a wide variety of effective PPE manufactured by numerous reputable manufacturers, the appropriate use of such equipment relies heavily on training and proper selection of equipment. Size, fit, and maintenance of PPE is essential to its efficacy, and therefore, proper employee training must be conducted before and periodically during the use of these projects. For these reasons, using PPE as a means of controlling occupational risks is the least reliable.

Conclusion

Occupational risks vary with the nature of the work environment. The economy in the United States has changed very rapidly in the past century. As the economy of a country changes, the structure of the work environment also changes. One specific example of this is how many American workers have experienced the shift in work from production factories to the service sector. With any type of shift in the work environment or work task, there will be a shift in the occupational hazards and risks as well. The most common types of occupation hazards in factories (e.g., severed digits due to unguarded machinery) are not the same as the most common types of occupational hazards that workers are experiencing in the service sector (e.g., exposure to pathogenic agents due to needle pricks). Acknowledging these dissimilarities and others such as those that may come from a change in the demographics of the workforce (e.g., higher percentage of women) or the development of new products resulting in new hazards (e.g., nanomaterials) is crucial to being able to appropriately recognize, evaluate, and control occupational risks.

Odds and Odds Ratio

The odds are an alternative way of quantifying chance. Readers are likely to be familiar with the concept from sports betting. In gambling, it is customary to state the chance of an event as the ratio of the number of times that it is expected to happen over the number of times that it is not – the so-called odds in favor of the event. For example, for a horse that previously won 4 races and lost 6, the chance of winning a future race might be stated by an odds of 4 over 6 ($4/6 = 0.67$) for winning or 6 over 4 ($6/4 = 1.5$) in favor of losing. (Odds are a useful currency in betting. This is because, when investing monies in support of or against a bet where the jackpot is divided between the winners, the odds representing the ratio of these monies translate directly into a winner's return per unit investment.)

Importantly, the odds of an event do not represent proportions, and so the odds of it happening and the odds of it not happening do not add up to one. Rather, due to its definition, the odds in favor of an event are the inverse of the odds against the event. Thus, for the horse racing example, while we might estimate that our horse has a $100 - 40 = 60\%$ risk of losing based on knowing that it won 40% of previous races, knowing that the odds in favor of winning are 0.67 would lead us to conclude that the odds for losing are $1/0.67 = 1.5$.

Odds can be compared between two groups by calculating a ratio. The *odds ratio* measures how the odds of an event, typically of getting a disease, varies between two categories, typically a group that is exposed to a risk factor and one that is not. The specific definitions are most easily understood in terms of a 2×2 table of exposure by disease as shown in Table 1. Therein, N denotes the population size and a , b , c , and d the

absolute frequencies of the respective combinations of the levels of the risk factor (exposed or not exposed) and the disease factor (present or absent). The odds of the disease within a subpopulation is then defined by the ratio of the number of subjects that have the disease over the number of those that have not, i.e., $o(\text{disease present}|\text{exposed group}) = a/b$ and $o(\text{disease present}|\text{nonexposed group}) = c/d$. The odds ratio (OR), of disease comparing the exposed with the nonexposed subpopulation is then given by the ratio

$$\text{OR} = \frac{a/b}{c/d} = \frac{a/c}{b/d} \quad (1)$$

For example, an odds ratio of coronary heart disease, comparing obese people with nonobese people, of two would be interpreted as a doubling of the odds of heart disease when putting on weight. Similarly, an odds ratio of contracting measles, comparing vaccinated children with nonvaccinated children, of 0.5 would be interpreted as a halving of the odds of contracting measles.

An appealing property of the odds ratio is that its population value can be estimated from most observational study designs. Specifically, while indices based on risk proportions, for example relative risk (see **Relative Risk**), cannot be estimated directly from *case-control studies* (see **Case-Control Studies**), this is possible for odds ratios. Mathematically, the odds ratio of disease, comparing the exposed with the nonexposed subpopulation, equates to the odds ratio of exposure, comparing cases (subpopulation with disease present) with controls (disease absent), with the latter being estimable from case-control designs. Case-control studies are frequently used in practice, and this explains the widespread use of the odds ratios as a measure of the effect of exposure on disease. In addition, the odds ratio is often used to approximate the relative

Table 1 Two-way classification of exposure by disease

		Disease		Total
		Present	Absent	
Risk factor	Exposed	a	b	$a + b$
	Not exposed	c	d	$c + d$
	Total	$a + c$	$b + d$	$N = a + b + c + d$

risk ratio of disease with this approximation holding when the disease is relatively rare (say less than 5% prevalence).

Operational Risk Development

Operational risk (*see* **Simulation in Risk Management; Operational Risk Modeling; Near-Miss Management: A Participative Approach to Improving System Reliability; Compliance with Treatment Allocation**) has rapidly moved up the agenda of all banks, largely in response to the positioning of operational risk as a Pillar 1 risk under Basel II (*see* **Credit Risk Models; Solvency; Informational Value of Corporate Issuer Credit Ratings; Risk in Credit Granting and Lending Decisions; Credit Scoring**). This means that for banks implementing Basel II, the capital requirement of the bank will in part be assessed on the basis of a “model” of its operational risks.

There are three approaches allowed under Basel II for assessing the capital a bank must hold against its operational risk:

- the basic indicator approach – fixed % gross income
- the standardized approach – % of eight business lines gross income
- the advanced measurement approach – internal model.

This article focuses on the advanced measurement approach because this is the only “model” that truly reflects a risk-based approach, as it mirrors (in many cases, also adds greater discipline to) the approach taken by the banks’ management themselves.

The decision to include operational risk computation as a contributor to banks’ minimum regulatory capital requirements (a so-called Pillar 1 risk under Basel II) was always likely to be controversial for a number of reasons:

- Conceptually, operational risk is not well defined. Indeed, it is not hard to find risk professionals who feel it is not really a risk discipline at all, and is often thought of as simply a “catch all” description for the residual risk not covered by market or credit risk.
- Operational risk events are normally categorized, for data collection purposes, as either high-frequency low-severity events or low-frequency high-severity events. Data collection under both

descriptors poses both conceptual and practical problems that may be difficult for banks to resolve.

- Data on operational risks is often said to be both unreliable and frequently unavailable.
- Some of the approaches to Operational Risk Measurement, particularly Op. VaR, are criticized for failing to provide any useful insight into the management of operational risk.

Defining Operational Risk

The Basel II definition of operational risk, “The risk of loss resulting from inadequate or failed internal processes, people and systems, or from external events” has a distinctly “catch all” flavor to it.

Whatever the technical definition of risk, anyone who deals with credit or market risk (*see* **Credit Risk Models; Securitization/Life; Default Risk; Compliance with Treatment Allocation**) will have a clear conception of risk and reward as “two sides of the same coin”. For instance, a rise in the dealing position limits within a dealing room will, all other factors remaining the same, lead to an overall greater return, but at the expense of greater volatility of return, and if that volatility produces a particularly bad outcome, the bank will need more capital to survive it. The same concept applies to credit risk; however, operational risk is different.

Efficient Operation of Bank Processes

When we look at operational risk, we observe that in some ways it conforms to many of the characteristics of typical process control issues. For instance, if we look at the efficient operation of a call center, one frequent observation is that inefficient centers are more costly to run (often because of the need to run a parallel set of “repair” processes), produce lower sales, and have a far greater incidence of losses owing to administrative errors. Improvements in the management and control of the operational processes can frequently produce higher returns, owing to lower costs and higher sales being accompanied by a reduced likelihood of incurring administrative losses.

It is this characterization of operational risk that tends to take it away from the discipline of risk management as it is applied to market or credit risk and firmly embed it in the discipline of process management and control. Thus, for management purposes,

this often leads banks to focus their operational risk reporting and management on ensuring that bank processes meet the best international industry standards, such as those covered by relevant International Organization for Standardization (ISO) standards, and by the use of well-trying process management techniques such as “six sigma”.

It also should lead the banking sector to learn from how other industries look at operational risk. For instance, the manufacturing industry is well advanced in its use of real-time signaling of potential problems as happens, say, when heat and vibration sensors on machines feed predictive models of machine breakdown and thus preinform maintenance and repair schedules. While applying such techniques to the banking sector requires research, original thought, and imagination, the potential for operational risk to materialize is surely, in part, increased when banking processes (be they machine driven or manual) “run hot”.

Categorizing Operational Risk Events

If positively defining operational risk is difficult, perhaps recourse to the data can help us characterize events and thus, by observation, develop both a more encompassing definition of operational risk and the data from which to feed appropriate models of operational risk.

An immediate conceptual problem is, however, that operational risk is perhaps not best defined simply in terms of bad outcomes (i.e., losses).

Indeed, by defining operational risk simply in terms of loss events, a bank could actually fail to record important operational risk events. The Basel II definition uses the term “risk of loss”, but this can be misleading, as not all operational risk events lead to banks incurring losses. It is possible for operational risk events to result in a profit, but such events should not be ignored, because they have the potential to result in a loss if they occur again.

Take the example of a bank that has a dealing desk that undertakes foreign exchange transactions. After one deal, the trader mistakenly books that he purchased yen against a sale of US dollars instead of what actually took place, a purchase of US dollars against a sale of yen. This makes it appear to the dealer that he is “long” in yen. To resolve the mismatch position, he decides to sell the yen he thinks he has and purchase dollars.

As a result of the original mistake, the dealer has actually doubled his US dollar mismatch instead of “squaring off” the position. Later in the day, the error is realized, and the trader sells his large US dollar position. Luckily for the trader, the dollar exchange rate has risen against the yen, and so he actually makes a profit.

In this example, the operational risk event (the incorrect recording of a spot foreign exchange transaction) resulted in the bank making a profit, not a loss. It should be recorded as an operational risk event, however, (usually termed a *near miss*) to help the bank improve its processes, because, it may not be so lucky next time. In this particular instance, it is important that the profit is not recorded as a trading profit.

This example, like that in defining operational risk, above, is an example of a high-frequency/low-impact event. These events tend to be readily understood and are viewed by many banks simply as “the cost of doing business”, particularly where the bank is convinced its processes are efficient.

Many financial products, particularly those in retail banking, will include a factor for these kinds of losses within their pricing structure. For example, many banks that offer credit card products adjust their pricing structure to account for a level of fraud they cannot avoid.

Unreliable and Unavailable Data

There is much concern among banks that they have not recorded data on operational risk events. While it must be true that all causes of loss are correctly recorded in the annual accounts (and thus operational risk data must exist), it is nonetheless true

- that such data has often not been recorded other than for accounting purposes and such data is often not suitable for operational risk analysis purposes. For example, operational risk events that are often a problem as profitable events (see the foreign exchange example above) are often systematically underrecorded (would the above profit be recorded as a dealing profit?).
- that individual banks have often suffered too few low-frequency/high-impact events to make any analysis of them meaningful.

In the former case, there are a number of changes to data recording practice that can improve the

situation. One of the world's largest banks has not only reviewed the recording of operational risk events and losses but has also ensured that it has a range of appropriate profit accounts with appropriate procedures to mitigate the systematic underrecording problem. While a certain amount of reconstruction of data is possible, it has to be admitted that for many banks initial operational risk data would be deficient against the standards their supervisors and their own model builders are likely to require.

Modeling Extreme Outcomes

Characterizing operational risk as closely related to process control is clearly necessary but is also clearly not sufficient. While we may observe that the bulk, by number, of bad outcomes in operational risk are so related, we can also see that many of the very worst outcomes, especially those that have led to banking collapses, are not solely explained by breakdowns in processes. In the case of Barings, the US Savings and Loans Crisis, and Long-Term Capital Management (LTCM) (and many more), clearly other factors were at work.

However, it is the low-frequency/high-impact events that are, by far, the most challenging for banks, both in terms of understanding their underlying ("root") causes and in terms of establishing a meaningful base of relevant data. By their very nature, such events are the least understood and the most difficult to predict. Furthermore, they have the potential to do severe damage and may even result in the collapse of the bank.

One problem of low-frequency/high-impact event recording (*see* **Potency Estimation; Extreme Values in Reliability; Near-Miss Management: A Participative Approach to Improving System Reliability**) is that it has "survivor bias" issues in that banks that suffer catastrophic loss events are likely, as a result of the event, to leave the industry. While this problem is well known, it is, nonetheless, very real, and leads to a systematic underestimation of the likelihood of such losses.

To mitigate this issue, and to ensure that banks can use distributions of outcomes that reflect industry experience rather than single bank experience, several data sharing projects have been initiated. This external data is used to perform benchmark analyses, and may also be used to perform scenario and stress analyses. To obtain external data, banks have entered into

data pooling arrangements with other banks. Such arrangements include the following:

- The Operational Riskdata eXchange Association (ORX)
- The British Bankers Association (BBA) Global Operational Loss Database (GOLD).

It is also important that banks use both stress tests and scenario analysis (*see* **Operational Risk Modeling**) to add insight to an understanding of their potential vulnerability to operational risk events. Stress tests, because of the paucity of even industry-wide data are often produced using Monte Carlo simulation (*see* **Environmental Monitoring; Risk Measures and Economic Capital for (Re)insurers; Simulation in Risk Management; Reliability Optimization**) techniques; such techniques, however, often show their greatest weakness when it comes to explaining the model results to senior management. It is very hard for anyone to give due weight in their decision making to events with very low probabilities of occurrence. For example, when traveling, how many of us assess the relative mortality rates for different modes of transport? In practice, most people confine the statistics on the likelihood of their dying as a result of traveling by car, train, ship, or airplane to a meeting to one "box" called *unlikely*. Focusing senior management attention on events with say a 1 : 10 000 likelihood of occurring is never easy, as they suffer from human behavior just like everyone else.

Scenario analysis on the other hand, whatever the probability of the scenarios occurrence, can bring any risk debate alive, especially when the scenario has some "official" backing. The Financial Services Authority of the United Kingdom produces each year their "Financial Risk Outlook", which makes a very useful basis for any banks scenario analysis.

Operational Risk Measurement – Op. VaR

From a technical, statistical perspective, it is possible to concatenate different distributions to produce a distribution that brings together high-frequency/low-impact events and low-frequency/high-impact events. However, such distributions may have limited explanatory power if the resulting distribution has outcomes that are a result of a wide variety of differing causes.

From this, we may conclude that a measure of risk such as value at risk (VaR) when used to measure

operational risk (Op. VaR) may not produce the same level of insight into the management of operational risk that similar measures produce in the case of market risk (M. VaR) or credit risk (C. VaR).

An example of this is that operational losses, by number, in banks will be from high-frequency/low-impact events, individually small, many resulting from “mistakes” in processing. Moreover, there will be a lot of such events, but their overall value will often be surprisingly stable over time, in relation to the number of transactions undertaken by the bank. This data may be extracted from the bank’s sundry profit and loss accounts and are easily incorporated into the price the bank charges its customers for a relevant service. As such, and provided they can evidence to its supervisor that the bank does incorporate the average level of such losses into its product pricing, then these losses will not affect the level of capital the bank must hold.

An Op. VaR measure of these outcomes is likely to produce a “well-behaved” elliptical distribution where “pricing in” the mean is relatively easy to achieve, and, if not “normal”, an analysis of the percentiles will show a high percentage of all outcomes within 2 to 3 standard deviations of the mean.

The incorporation of low-frequency/high-impact events in the distribution that frequently have very different causes will produce a tail of the distribution that needs to be focused on for cause of the obviously extreme outcomes. Indeed, given the size of these extreme outcomes and the contribution of these outcomes to capital requirements, it is this part of the distribution that is of greatest interest to chief risk officers.

This points to another limitation of Op. VaR, for if it is the tail of the distribution of outcomes in operational risk that is most interesting, then one would have strong reservations about using VaR to measure it, as VaR is not a measure of tail risk, but a measure of variance around central tendency. It would seem more logical to start with a measure that looks directly at the tail data, say expected shortfall (ES) (*see **Extreme Value Theory in Finance; Compliance with Treatment Allocation***). As ES also has the feature of being a measure used extensively in the insurance industry to price risks, it should also inform a common framework for banks and insurers to allow banks to insure some of their tail risk through insurance contracts. This contingent capital approach, called so because the payout under the

insurance contract is effectively an injection of free capital available to absorb losses, should grow in the future, as Basel II allows insurance as a risk mitigation technique.

Conclusions

- Only the implementation of an advanced measurement approach to operational risk is likely to add value to a bank’s management of operational risk.
- The measurement and management of high-frequency low-impact operational risk events is best treated as an exercise in process management and control, but there is room for innovative approaches based on methodologies used in other industries.
- Data on operational risk presents problems both in definition and collection that are not commonly met in collecting credit and market risk data. To improve operational risk data requires cooperation between banks and change to internal management and accounting processes.
- Operational value at risk (Op. VaR) may have limited explanatory powers, as outcomes are the result of widely differing causes, and Op. VaR, as a pricing tool, is inferior to measures such as ES, a measure widely used in the insurance industry. As Basel II allows insurance as a risk mitigation technique, this difference in measurement techniques may inhibit the insurance of operational risk.

Operational Risk Modeling

Operational Risk Definition and Database Modeling

An operational risk (*see Solvency; Extreme Value Theory in Finance; Near-Miss Management: A Participative Approach to Improving System Reliability*) loss can be defined as a negative impact on the earnings or equity value of the firm owing to an operational risk event. An operational risk event is an incident that happens because of inadequate or failed processes, people or systems, or due to external facts and circumstances; basically it involves any procedural error in processing transactions or any external events (legal suit, terrorism, etc.).

The tracking of internal operational loss data is essential to the entire operational risk management and measuring process. This data must be collected and organized in a time series. The internal loss database is fundamental in the estimation of economic capital to cover against operational risk.

The operational loss data should be collected straight from the profit and loss (P&L) and related systems whenever it is possible and economically feasible. The basis for this logic lies in the fact that when an operational risk loss affects assets or accounts maintained on a mark-to-market basis, the economic impact of the event is usually the same as the accounting impact. In such cases, the basis for measurement is the loss adjustment as recognized in the P&L system.

Internal Loss Data Characteristics

To model operational risk, a financial institution needs to first establish a database with internal historical losses. There are a number of regulatory and technical prerequisites that the firm must follow to attend minimum supervisory and modeling requirements. A bank's internal loss data must be thorough in that it captures all material activities and exposures from all appropriate subsystems and geographic locations; therefore, the internal loss data program covers firmwide operational losses with the participation of every business unit in all the banks' locations

throughout the world. A minimum threshold for data collection could also be established for the collection of internal loss data.

Definition of Gross Loss Amount

The gross operational loss should include the following:

- charges to the P&L and write downs owing to operational risk events;
- market losses owing to operational risk events;
- payments made to third parties for lost use of funds, net of amounts earned on funds held, pending a late payment;
- in cases where a single event causes both positive and negative impacts, the two should be netted. If the net amount is negative and exceeds the reporting threshold, it should be submitted;
- loss is determined at the time of the event, without regard to any eventual remediation. Thus, for example, if a security is bought when a sale was intended, the market value as on the day of the transaction is considered for purposes of calculating the losses, even if the security is held for a period of time until a more favorable market environment develops;
- it is understood that certain losses happen in core functions not directly involved with the P&L, like the IT department, for example. Losses happening in such departments should also be reported as long as they meet the conditions mentioned above;
- operational risk losses that are related to market risk are to be treated as operational risk for the purposes of calculating minimum regulatory capital (e.g., misrepresentation of market positions or P&L caused by operational errors, stop loss violations, losses produced by market valuation models that fail to work properly for any reason, losses taken from market positions taken in excess of limits etc.);
- legal risk is considered operational risk and should be reported. Events related to legal risk usually are disputes that may include litigation in court, arbitration, claims negotiation, etc.
- Some operational risks embedded in credit risk should be reported such as:
 - procedure failures – where processing errors prevent recovery on a loan or actually enable

a loss, as where a cash advance is made on a credit facility that was earlier cancelled by a credit officer;

- legal issues – loan documents that may contain legal errors (invalid clauses or terms etc.);
- scoring models – errors in scoring models might result in the approval of transactions that would otherwise not be admitted.

Exclusions from the Definition of Gross Loss Amounts

The following events should *not* be included in the gross loss:

- internal reworks (cost of repair and/or replacement), overtime, investments, etc.;
- near misses (potential losses that have not materialized);
- costs of general maintenance contracts on equipment, etc. even if used for repairs or replacements in connection with an operational risk event;
- events causing only reputational damage. Reputational risk is *not* considered operational risk. Reputational risk is the risk of any damage to the firm's reputation caused by internal or external factors;
- losses arising from flawed strategic or discretionary processes are *not* recordable, as such losses are considered the result of business or strategic risks. This type of risk is associated often with senior management decision making (e.g., merger and acquisition decisions, regional or global strategy, etc.).

Firms should also collect external loss data, which can be used either by mixing it with the internally collected data points or used to develop scenario analysis and/or stress tests. Self-assessment type of subjective opinion on potential losses is also approved by the regulators although it is not indicated how it should be used in the framework. Firms should also establish and collect business and control environment factors. All these elements (internal data, external data, scenario analysis, and business and control factors) should be used in the measurement framework.

Measuring Operational Risk

Introduction to the Measurement Framework

According to the new Basel Accord established in June 2004, financial institutions should allocate capital against operational risk. They have three options to choose from – the basic indicator, the standardized approach, and the advanced measurement approach (AMA). In the AMA approach, financial institutions may develop their own models to measure and manage operational risk. To establish some ground rules for such models, there are a series of standards that must be followed by the financial institutions to be able to use them as determined by the Basel Accord.

It is possible that a number of models would have to be developed to cope with the different types of data that need to be used by regulatory requirement – the risk measurement (value at risk (VaR) model (*see Equity-Linked Life Insurance; From Basel II to Solvency II – Risk Management in the Insurance Sector; Credit Value at Risk; Compliance with Treatment Allocation*)), the causal model, and the scenario analysis model. Each model covers a different aspect of operational risk, thereby supplementing one another. The overall risk measurement outline might be thought of in terms of capital estimation, in which the following three layers of coverage are usually considered by firms: expected losses, unexpected losses, and catastrophic losses. Expected losses are not considered risks as these are amounts a firm presumes to lose in a given period and, therefore, would not demand capital but would be covered through provisions, or would be embedded in the pricing of the product. Unexpected losses are considered as risk and would demand capital. There are also the high, very infrequent losses (“catastrophic”) that, would not necessarily demand capital because they have a very low probability of occurrence, but, nevertheless, need to be fully understood to be avoided.

In regard to the models used to assess these three levels of estimation, the expected losses can be seen as simply the expected average of the losses for a certain period. The unexpected losses can be estimated by VaR type of models and the “catastrophic” (or extreme) losses can be estimated by scenario analysis or by performing stress tests. The causal model includes key risk indicators to the analysis and tries to find relationships and correlations between these and the losses. This type of analytical framework helps

to identify the indicators that play an influential role in determining the losses.

Operational VaR Model

The VaR type of models, whose development began in the early 1990s, is currently considered as the standard measure for market risk and has even been extended to credit risk measurement. From the viewpoint of market risk, VaR measures the estimated losses that can be expected to be incurred within a certain confidence interval, in the market value of a portfolio until the position can be neutralized. In other words, VaR estimates losses resulting from holding a portfolio for a determined period using the asset prices over the last n days as a measure of the volatility.

A similar logic can be applied in operational risk. However, as the underlying stochastic processes in market and operational risks are different, changes have to be made in the framework developed for the market VaR. In operational risk, two separate stochastic processes that are investigated are as follows: the frequency (*see Experience Feedback; Operational Risk Development*) and the severity (*see Compensation for Loss of Life and Limb; Potency Estimation; Risk Measures and Economic Capital for (Re)insurers*) of the losses. The operational VaR is the aggregation of these processes, i.e., the aggregated loss distribution. Putting it simply, $\text{VaR} = \text{frequency} \times \text{severity}$.

In more formal terms, the aggregated losses at time t given by $X(t) = \sum_{i=1}^{N(t)} U_i$ have the distribution function (where U represents the individual operational losses)

$$F_{I(t)}(x) = \Pr(X(t) \leq x) = \Pr\left(\sum_{i=1}^{N(t)} U_i \leq x\right) \quad (1)$$

The derivation of an explicit formula for $F_{I(t)}(x)$ is, in most cases, impossible. It is usually assumed that the processes $\{N(t)\}$ and $\{U_n\}$ are stochastically independent. Deriving the formula above, we observe the following fundamental relationship:

$$\begin{aligned} \text{VaR}_{OR} &= F_{I(t)}(x) = \Pr(X(t) \leq x) \\ &= \Pr\left(\sum_{t=0}^{\infty} P_t(t) F_U^{\bullet t}(x)\right) \end{aligned} \quad (2)$$

where $F_U^{\bullet t}$ refers to the t th convolution of U with itself, i.e., $F_U^{\bullet t}(x) = \Pr(U_1 + \dots + U_t \leq x)$, the distribution function of the sum of k independent random variables with the same distribution as U .

More practically, the operational VaR model takes a time series of internal loss data as inputs and tries to use this data set to estimate losses, at several confidence intervals, for different periods ahead.

Extreme Value Theory. The typical operational loss database presents a distribution that is not Gaussian. In general, an operational risk database is composed of a few large events and several smaller ones. For risk-management purposes, the interest is to understand the behavior of the tail of the curve (or the most significant losses). One way of dealing with this type of situation is to use certain types of distributions that fit these patterns of events very well. These distributions are consolidated under the extreme value theory (EVT) (*see Individual Risk Models; Mathematics of Risk and Reliability: A Select History; Copulas and Other Measures of Dependency; Compliance with Treatment Allocation*). The application of EVT is used for severity distributions and it only works with the largest events of a database (above a certain threshold). For more details, please refer to [1].

Causal Model (Multifactor Model)

Although the operational VaR model estimates the risk level, it fails to explain the influence that internal factors play in determining these estimates. This is an important feature in risk-management models. Just for comparison, in the market risk VaR, risk analysts can easily verify the impact of any changing factor (e.g., increasing interest rates) in the VaR figures by stress testing the model. Considering the structural differences between market and operational VaR models, this would not be possible in the operational model because the necessary factors are not embedded in the model as they are in the market risk model. To overcome this limitation, an additional model would have to be developed incorporating the use of internal factors (key risk indicators) as inputs to explain which manageable factors are important for determining the operational losses.

One way of dealing with causal models (*see Modifiable Areal Unit Problem (MAUP); Risk from Ionizing Radiation; Uncertainty Analysis*

and Dependence Modeling; Statistical Arbitrage) is to consider the relationship between the dependent and independent variables as linear and apply multifactor models to explain the losses. Basically, such models try to relate losses to a series of key risk indicators suggesting the following relationship:

$$Y_t = \alpha_t + \beta_1 X_{1t} + \dots + \beta_n X_{nt} + \varepsilon_t \quad (3)$$

where Y represents the operational losses in a particular business during a particular period and X represents the key risk indicators. The α 's and β 's are the estimated parameters.

There are several approaches to estimate the parameters of the model, but one of the most popular ones is the ordinary least-squares (OLS) method. In summary, this method basically solves the equation above for ε_t and minimizes

$$\hat{\varepsilon}_t = Y_t - \hat{\alpha}_1 - \hat{\alpha}_2 X_{1t} \quad \text{or} \quad \hat{\varepsilon} = Y_i - \hat{Y}_i \quad (4)$$

The OLS method squares the residuals and minimizes their sum by solving the problem

$$\min \sum \hat{\varepsilon}_t^2 = \sum (Y_t - \hat{\alpha}_1 - \hat{\alpha}_2 X_{1t})^2 \quad (5)$$

The parameters that solve the above equation for the minimum value of the residuals are selected.

The Scenario Analysis Model

Owing to fact that large/catastrophic events, because of their exceptionality, should not happen frequently, historical loss data alone might not be a good indicator of the operational risk level of the firm, at least in the early stages of the measurement process. Considering these facts, the operational VaR model might also have some limitations in performing robust estimation of large/infrequent events. By including scenario analysis (*see Managing Infrastructure Reliability, Safety, and Security; Dynamic Financial Analysis*) as a supplementary model, decisions on both capital and operational risk management can be based on more information than these initially scarce data collected internally. Scenario analysis can provide useful information about a firm's risk exposure that VaR methods can easily miss, particularly if VaR models focus on the "regular" risk rather than the risks associated with rare or extreme events. Such information can then be fed into strategic planning, capital allocation, hedging, and other major decisions.

The measure of operational risk can be seen as the aggregation of severity and frequency of losses over a given time horizon. The severity and frequency of the losses can easily be linked to the evaluation of scenarios, crystallized as potential future events. Their evaluation would involve learning how the frequency and severity would be affected by extreme environments.

To start the modeling process of a scenario analysis, it is necessary to develop a clear procedure for generating a representative set of scenarios that takes into account all relevant risk drivers that might influence its control environment, which ultimately determines the operational risk level. Understanding the relationship of these risk drivers with the frequency, severity, or aggregated operational losses is important in the development of these scenarios as they make it easier to incorporate expert opinions into the model. The risk drivers are then categorized and give rise to scenario classes (e.g., system crashes).

There are quite a few ways to generate these scenarios. Some of them include stressing the parameters or results of the VaR and causal models. In accordance with the operational risk measure, the scenario analysis process must lead to an evaluation of the potential frequency and severity of the financial impact of particular scenarios. The scenario analysis would consider every input available such as expert opinion, key risk indicators, historical internal losses, and any relevant external events. The weighting attributed to each would depend on the quality of the information available. An overview of the scenario analysis model framework would be as in Table 1.

The envisaged scenario analysis model would deal with different ways to generate scenarios from the different inputs and models and help in the validation process.

The scenario analysis process is a complex one and involves more than just quantitative analysis. It implicates also the analysis of shocks and how they would affect a particular business unit or the entire firm.

The scenario analysis process starts by defining the risk profile of a certain business unit and then proceeds by investigating how the business would behave given a series of hypotheses that might be arbitrary or historical (based on events that happened in the past with this firm or another firm), and

Table 1 Scenario analysis framework

Inputs	Scenario generation	Model	Validation
Expert opinion	Scenario analysis model	Estimate loss distributions from expert opinions	Use of internally generated distributions to compare
External data	Scenario analysis model	Analyze sensitivity of external events in the firm Compare external loss distributions with internally generated ones	Use of loss data and expert opinions to compare Use of internally generated distributions to compare (statistical tests may apply)
Key risk indicators	Causal model	Turn explanatory variables stochastic Use upper range of model parameters confidence interval	Quantitative Quantitative
Internal losses	VaR model	Stress model parameters Use of extreme value theory	Quantitative Quantitative

Table 2 Hypothesis tests for scenario analysis and sources of data

Test of hypothesis	Source of data	Note
Historical shocks	Internal experience, external data	The external data available in the databases can be analyzed to estimate their eventual impact on the firm considering the firm's specific control environment. In addition to this, in case the firm experienced large events in a particular type of situation, these can also be used.
Arbitrary shocks	Expert opinions, internal data, KRIs	The arbitrary shocks might be designed on the basis of expert opinions collected from the BSA or even be developed from workshops.
Sensitivity tests	All available	Aim at understanding the changing variance in the correlation between the several KRIs and the loss data, and the eventual extreme losses arising from that. These relationships can be stressed to verify their impact on the P&L.

sensitivity tests. A summary of the hypothesis tests can be seen in Table 2.

The scenario analysis for operational risk involves all data sources, in addition to sensitivity tests that aim at estimating extreme losses that might arise from negative situations. These hypotheses defined by the shocks and the sensitivity tests are also further tested and benchmarked in a second stage.

Framework Integration

The overall framework should be composed of the following three key elements: the database, the models, and the outcomes. The database, as described in the Section titled "Operational Risk Definition and Database Modeling" of this article, is composed not only of the time series of the internal losses and key risk indicators, but also includes expert opinion collected from the business self-assessment process and

external data. These inputs feed the operational VaR, the causal, and the scenario analysis models. Interfaces between the database and the models have to be developed, allowing the users of the models to load data from different databases. These models allow the estimation of economic and regulatory capital, performance of sensitivity and cost/benefit analysis, and performance of a more proactive operational risk management. Among the outcomes of the models are also the official periodic reports to be submitted to the regulators.

Conclusion

Operational risk modeling has evolved significantly since it was first introduced in the mid-1990s. Virtually every financial institution of a reasonable size would have a team or at least someone responsible for the management of operational risk. The

models presented here are just a blueprint of what can really be done to measure and manage this risk. Many other aspects should be taken into consideration like the use of hedge (insurance), correlations—dependence, etc. This is still a young area with quite a lot of potential to develop. Books like [2] describe a number of approaches and techniques that can be used in operational risk.

Optimal Risk-Sharing and Deductibles in Insurance

Deductibles, in some form or other, are often part of real-world insurance contracts, but most of the classical theory of risk sharing is unable to explain this phenomenon. In this paper, we discuss deductibles from the perspective of economic risk theory and try to point out when optimal contracts contain deductibles.

The model we consider is a special case of the following: consider a group of I agents that could be consumers, investors, reinsurers (syndicated members), insurance buyers etc., having preferences over a suitable set of random prospects. These preferences are assumed to be represented by expected utility (*see Utility Function*), which means that there is a set of utility functions $u_i : R \rightarrow R$, such that X is preferred to Y if and only if $Eu_i(X) \geq Eu_i(Y)$. Here, the random variables X and Y may represent terminal wealth or consumption in the final period. They could also represent insurance risks by a proper reformulation. We assume smooth utility functions with the properties that more is preferred to less, i.e., these functions are strictly increasing, and that the agents are risk averse, i.e., these functions are all concave.

Each agent is endowed with a random payoff X_i called his *initial portfolio*. Uncertainty is objective and external, and there is no informational asymmetry. All parties agree upon the space $(\Omega, \mathcal{F}, P)$ as the probabilistic description of the stochastic environment, the latter being unaffected by their actions. Here, Ω is the set of states of the world, $\mathcal{F}$ is the set of events, formally a σ field generated by the given initial portfolios X_i , and P is the common belief probability measure. For the sake of convenience, it is proposed that both expected values and variances exist for all the initial portfolios, since this is true in real life applications of the theory.

We suppose that the agents can negotiate any affordable contracts among themselves, resulting in a new set of random variables Y_i , representing the possible final payout to the different members of the group, or final portfolios. The transactions are carried out right away at “market prices”, where $\pi(Y)$ represents the market price for any nonnegative random variable Y , and signifies the group’s common valuation of Y relative to the other random variables

having finite variance. The essential objective is then to determine the following:

1. the market price $\pi(Y)$ of any “risk” Y from the set of preferences of the agents and the joint probability distribution of the X_i ’s;
2. the final portfolio Y_i most preferred by each individual, from among those satisfying his budget constraint. Finally, market clearing requires that the sum of the Y_i ’s equals the sum of the X_i ’s, denoted X_M .

The outline of the paper is as follows: In the section titled “Risk Tolerance and Aggregation”, we define key concepts like Pareto optimality and risk tolerance (aversion), and give Borch’s characterization of Pareto optimality. In our subsequent treatment, we more or less take for granted the concepts of a competitive equilibrium, Borch’s theorem, as well as the representative agent construction that leads to the solution of 1 and 2 above. With this as a starting point, in the section titled “The Risk Exchange between an Insurer and a Policy Holder”, the above general formulation is applied to the problem of finding the optimal risk exchange between an insurer and a policy holder. In this section, we also present a simple, motivating example. Deductibles in the optimal contracts are treated in the section titled “Deductibles”. First, we discuss deductibles stemming from no frictions, then those arising from administrative costs, and finally deductibles from moral hazard (*see Moral Hazard*). The final section “Conclusions” is a brief summing up.

A glaring omission in our treatment of deductibles is that of adverse selection. Rothschild and Stiglitz [1] showed in their seminal paper that the presence of high-risk customers caused the low-risk customers to accept a deductible. Since the analysis of this problem deviates quite substantially from the treatment in the rest of the paper, we have omitted it. Adverse selection is, however, another prominent example of asymmetric information that causes deductibles and less than full insurance to be optimal.

Risk Tolerance and Aggregation

We first define what is meant by a Pareto optimum. The concept of *Pareto optimality* offers a minimal and noncontroversial test that any socially optimal

economic outcome should pass. In words, an economic outcome is Pareto optimal if it is impossible to make some individuals better off without making some other individuals worse off.

Karl Borch's characterization of a Pareto optimum $Y = (Y_1, Y_2, \dots, Y_I)$ simply says that there exist positive "agent" weights λ_i such that the marginal utilities at Y of all the agents are equal modulo these constants, i.e.,

$$\begin{aligned} \lambda_1 u'_1(Y_1) &= \lambda_2 u'_1(Y_2) \cdot \dots = \lambda_I u'_1(Y_I) \\ &= u'_\lambda(X_M) \quad a.s. \end{aligned} \quad (1)$$

The function $u'_\lambda(\cdot)$ is interpreted as the marginal utility function of the representative agent. The risk tolerance function of an agent $\rho(x) : R \rightarrow R_+$, is defined by the reciprocal of the absolute risk aversion function $R(x) = -\frac{u''(x)}{u'(x)}$, where the function u is the utility function in the expected utility framework. Consider the following nonlinear differential equation:

$$Y'_i(x) = \frac{R_\lambda(x)}{R_i(Y_i(x))} \quad (2)$$

where $R_\lambda(x) = -\frac{u''_\lambda(x)}{u'_\lambda(x)}$ is the absolute risk aversion function of the representative agent, and $R_i(Y_i(x)) = -\frac{u''_i(Y_i(x))}{u'_i(Y_i(x))}$ is the absolute risk aversion of agent i at the Pareto optimal allocation function $Y_i(x)$, $i \in \mathcal{I}$. There is a neat result connecting the risk tolerances of all the agents in the market to the risk tolerance of the representative agent in a Pareto optimum: *1. The risk tolerance of "the market", or the representative agent, $\rho_\lambda(X_M)$ equals the sum of the risk tolerances of the individual agents in a Pareto optimum, or*

$$\rho_\lambda(X_M) = \sum_{i \in \mathcal{I}} \rho_i(Y_i(X_M)) \quad a.s. \quad (3)$$

2. The real, Pareto optimal allocation functions $Y_i(x) : R \rightarrow R$, $i \in \mathcal{I}$ satisfy the nonlinear differential equations (2).

The result in 1 was first stated by Wilson [2], and later also by Borch [3]. It is, in fact, a direct consequence of Borch's Theorem; see also Bühlmann [4] for the special case of exponential utility functions.

The result has several important consequences, one of which is as follows: suppose there is a risk neutral agent. In a Pareto optimum the entire risk will be borne by this agent.

The Risk Exchange between an Insurer and a Policy Holder

Some of the issues that may arise in finding optimal insurance contracts are, perhaps, best illustrated by an example:

Example 1 A potential insurance buyer can pay a premium αp and thus receive insurance compensation $I(x) = \alpha x$ if the loss is equal to x . He then obtains the expected utility

$$U(\alpha) = E\{u(w - X - \alpha p + I(X))\} \quad (4)$$

where $0 \leq \alpha \leq 1$ is a constant of proportionality. It is easy to show that if $p > EX$, it will *not* be optimal to buy full insurance, i.e., $\alpha^* < 1$ (see e.g., Mossin [5]).

On the other hand, the following approach was suggested by Karl Borch [6]. The situation is the same as in the above, but the premium functional is $p = (\alpha EX + c)$ instead, where c is a nonnegative constant. It follows that here $\alpha^* = 1$, i.e., full insurance is indeed optimal:

$$\begin{aligned} Eu(w - X + I(X)) \\ - EI(X) - c \leq u(w - EX - c) \end{aligned} \quad (5)$$

which follows by Jensen's inequality, in fact for *any* compensation function $I(\cdot)$. Equality is obtained in the above when $I(x) = x$, i.e., full insurance is optimal (if c is small enough such that insurance is preferred to no insurance). In other words, we have just demonstrated that the optimal value of α equals one.

The seeming inconsistency between the solutions to these two problems has caused some confusion in the insurance literature. In the two situations of Example 1, we only considered the problem of the insured. Let us, instead, take the step of including both the insurer and the insurance customer, in which case "optimality" would mean Pareto optimality.

Consider a policy holder having initial capital w_1 , a positive real number, and facing a risk X , a nonnegative random variable. The insured has the utility function u_1 , where monotonicity and strict risk aversion prevails, $u'_1 > 0$, $u''_1 < 0$. The insurer has the utility function u_2 , $u'_2 > 0$, $u''_2 \leq 0$, so that risk neutrality is allowed; initial reserve is given by w_2 , also a positive real number. These parties

can negotiate an insurance contract, stating that the indemnity $I(x)$ is to be paid by the insurer to the insured if claims amount to $x \geq 0$. It seems reasonable to require that $0 \leq I(x) \leq x$ for any $x \geq 0$. Notice that this implies that no payments should be made if there are no claims, i.e., $I(0) = 0$. The premium p for this contract is payable when the contract is initialized.

We recognize that we may employ our established theory for generating Pareto optimal contracts. In doing so, Moffet [7] was the first to show the following:

The Pareto optimal, real indemnity function $I: R_+ \rightarrow R_+$, satisfies the following nonlinear, differential equation

$$\frac{\partial I(x)}{\partial x} = \frac{R_1(A)}{R_1(A) + R_2(B)} \quad (6)$$

where $A = w_1 - p - x + I(x)$ and $B = w_2 + p - I(x)$, and the functions $R_1 = -\frac{u_1''}{u_1'}$, and $R_2 = -\frac{u_2''}{u_2'}$ are the absolute risk aversion functions of the insured and the insurer, respectively.

In our setting, this result is an immediate consequence of the result 2 of the previous section, provided the premium p is taken as a given constant.

From this result, we conclude the following: If $u_2'' < 0$, it follows that $0 < I'(x) < 1$ for all x , and, together with the boundary condition $I(0) = 0$, by the mean value theorem it follows that

$$0 < I(x) < x, \quad \text{for all } x > 0 \quad (7)$$

implying that *full insurance is not Pareto optimal when both parties are strictly risk averse*. We note that the natural restriction $0 \leq I(x) \leq x$ is not binding at the optimum for any $x > 0$, once the initial condition $I(0) = 0$ is employed.

We also observe that *contracts with a deductible d cannot be Pareto optimal when both parties are strictly risk averse*, since such a contract means that $I_d(x) = x - d$ for $x \geq d$, and $I_d(x) = 0$ for $x \leq d$ for $d > 0$, a positive real number. Thus either $I_d' = 1$ or $I_d' = 0$, contradicting $0 < I'(x) < 1$, for all x .

However, when $u_2'' = 0$, we notice that $I(x) = x$, for all $x \geq 0$. *When the insurer is risk neutral, full insurance is optimal and the risk neutral part, the insurer, takes all the risk*. Clearly, when R_2 is uniformly much smaller than R_1 , this will approximately be true even if $R_2 > 0$.

This gives a neat resolution of the ‘‘puzzle’’ in Example 1. We see that the premium p does not really enter the discussion in any crucial manner when it comes to the actual form of the risk-sharing rule $I(x)$, although this function naturally depends on the parameter p .

Deductibles

No Frictions

The usual explanation of deductibles in insurance goes *via* the introduction of some frictions of the neo-classical model. There are a few notable exceptions, one of which is as follows: the common model of insurance takes the insurable asset as given, and then finds the optimal amount of insurance given some behavioral assumptions. To explain the wealth effect in insurance, Aase [8] uses a model where the amount in the insurable asset is also a decision variable. In this situation, solutions can arise where the insurance customer would like to short the insurance contract, i.e., $I^*(x) < 0$ for some losses $x > 0$, for the optimal solution I^* . Since this violates $I^* \in [0, x]$, a deductible naturally arises, since no insurance then becomes optimal at strictly positive losses.

In fact, this seems to be the most common reason why deductibles also arise under frictions; when some constraint becomes binding at the optimum, usually caused by a friction, a deductible may typically arise.

The first case we discuss in some detail is that of administrative costs.

Administrative Costs

The most common explanation of deductibles in insurance is, perhaps, provided by introducing costs in the model. Intuitively, when there are costs incurred from settling claim payments, costs that depend on the compensation and are to be shared between the two parties, the claim size ought to be beyond a certain minimum in order for it to be Pareto optimal to compensate such a claim.

First we note that Arrow [9] has a result where deductibles seem to be a consequence of risk neutrality of the insurer.

Following Raviv [10], let the costs $c(I(x))$ associated with the contract I , and claim size x , satisfy $c(0) = a \geq 0$, $c'(I) \geq 0$ and $c''(I) \geq 0$, for all $I \geq 0$;

in other words, the costs are assumed increasing and convex in the indemnity payment I , and are *ex post*.

Raviv then shows that if the cost of insurance depends on the coverage, then a nontrivial deductible is obtained. Thus Arrow's [9, Theorem 1] deductible result was not a consequence of the risk-neutrality assumption (see also Arrow [11]). On the other hand, it was obtained because of the assumption that insurance cost is proportional to coverage. His theorem is then a direct consequence of the above-cited result. A consequence of this is the following: *If $c(I) = kI$ for some positive constant k , and the insurer is risk neutral, the Pareto optimal policy is given by*

$$I(x) = \begin{cases} 0, & \text{if } x \leq d \\ x - d, & \text{if } x > d \end{cases} \quad (8)$$

where $d > 0$ if and only if $k > 0$.

Here, we obtain full insurance above the deductible. If the insurer is strictly risk averse, a nontrivial deductible would still result if $c'(I) > 0$ for some I , but now there would also be coinsurance (further risk sharing) for losses above the deductible.

Risk aversion, however, is not the only explanation for coinsurance. Even if the insurer is risk neutral, coinsurance might be observed, provided the cost function is a strictly convex function of the coverage I . The intuitive reason for this result is that cost function nonlinearity substitutes for utility function nonlinearity.

A more natural cost function than the one considered above, would, perhaps, be a zero cost if there is no claim, and a jump at zero to $a > 0$ say, if a small claim is incurred. Thus, the overall cost function is $a\chi_{[I>0]} + c(I)$, where $c(0) = 0$, χ_B being the indicator function of B . Then, as long as $I < a$, it is not optimal for the insured to get a compensation, since the cost, through the premium, outweighs the benefits, and a deductible will naturally occur, even if $c' \equiv 0$.

To conclude this section, we note that a strictly positive deductible occurs if the insurance cost depends on the insurance payment, and also if a cost at zero is initiated by a strictly positive claim. Coinsurance above the deductible $d \geq 0$ results from either insurer risk aversion or cost function nonlinearity. For further results on costs and optimal insurance, see e.g., Spaeter and Roger [12].

Moral Hazard

A situation involving moral hazard is characterized by a decision taken by one of the parties involved (the insured), that only he can observe. The other party (the insurer) understands what decision the insured will take, but cannot force the insured to take any particular decision by a contract design, since he cannot monitor the insured.

The concept of moral hazard has its origin in marine insurance. The old standard marine insurance policy of Lloyd's – known as *SG* (ship and goods) policy – covered “physical hazard”, more picturesquely described as “the perils of the sea”. The “moral hazard” was supposed to be excluded, but it seemed difficult to give a precise definition of this concept. Several early writers on marine insurance (e.g., Dover [13], Dinsdale [14] and Winter [15]) indicate that situations of moral hazard were met with underwriters imposing an extra premium.

The idea that follows was initiated by Holmström [16]. To explain this, as in the above, let $u_2(x)$ and w_2 denote the insurer's utility function and initial wealth; $u_1(x)$, w_1 are similarly the corresponding utility function and initial wealth of the insured. In the latter case, the function $v(a)$ denotes *disutility* of level of care (or effort for short) and a the effort designated to minimize or avoid the loss. Only the insured can observe a . The loss facing the insured is denoted by X , having probability density function $f(x, a)$. We consider here, the part of the level of care that is unobservable by the insurer. Many insurance contracts are contingent upon certain actions taken by the insured, actions that can be verified or observed by the insurer. In this instance, we only consider nonobservable level of care.

In doing so, we deviate from the neoclassical assumption that uncertainty is exogenous, since the stochastic environment is now affected by the insured's actions.

The problem may be formulated as follows:

$$\max_{I(x), a, p} Eu_2(w_2 - I(X) + p)$$

where $I(x) \in [0, x]$, $p \geq 0$, subject to

$$Eu_1(w_1 - X + I(X) - p) - v(a) \geq \bar{h} \quad (9)$$

and

$$a \in \operatorname{argmax}_{a'} \{Eu_1(w_1 - X + I(X) - p) - v(a')\}$$

The first constraint is called the *participation Constraint* (individual rationality), and the last one is called the *incentive compatibility constraint*. This latter is the moral hazard constraint, and implies that the customer will use the effort level a that suits him best; this is feasible, since the insurer does not observe a . Technically speaking, the natural requirement $0 \leq I(x) \leq x$ will be binding at the optimum, and this causes a strictly positive deductible to occur. We illustrate this using an example:

Example 2 Consider the case with $u_2(x) = x$, $u_1(x) = \sqrt{x}$, $v(a) = a^2$, and the probability density of claims $f(x, a) = ae^{-ax}$ is exponential with parameter a (effort). Notice that $P(X > x) = e^{-ax}$ decreases as effort a increases: an increase in effort decreases the likelihood of a loss X larger than any given level x .

We consider a numerical example where the initial certain wealth of the insurer $w_1 = 100$, and his alternative expected utility $\bar{h} = 19.60$. This number equals his expected utility without any insurance. In this case, the optimal effort level is $a^* = 0.3719$.

In the case of no moral hazard, we solve the problem without the incentive compatibility constraint, and obtain what is called *the first best solution*. As expected, since the insurer is risk neutral, full insurance is optimal: $I(x) = x$, and the first best level of effort $a^{\text{FB}} = 0.3701$, smaller than that without insurance, which is quite intuitive.

The expected utility of the representative agent may be denoted by the welfare function. It is given by

$$Eu_2(w_2 + p - I(X)) + \lambda(Eu_1(w_1 - p - X + I(X)) - v(a)) = w_2 + 195.83 \quad (10)$$

since $\lambda = \lambda^{\text{FB}} = 9.8631$. Here $p^{\text{FB}} = 2.72$. Moving to the situation with moral hazard, full insurance is no longer optimal. We get a contract with a deductible d , and less than full insurance above the deductible:

$$I(x) = \begin{cases} 0, & \text{if } 0 \leq x \leq d \\ x + p - w_1 + (\lambda + \frac{\mu}{a} - \mu x)^2, & \text{if } d < x \leq \frac{\lambda}{\mu} + \frac{1}{a} \\ x + p - w_1, & \text{if } x > \frac{\lambda}{\mu} + \frac{1}{a} \end{cases} \quad (11)$$

Here the deductible $d = 11.24$, and the second best level of effort $a = a^{\text{SB}} = 0.3681$. We note that this is lower than a^{FB} . The Lagrangian multipliers of the two constraints are $\lambda^{\text{SB}} = 9.7214$ and $\mu = 0.0353$. The second best premium in this case is $p^{\text{SB}} = 0.0147$.

Owing to the presence of moral hazard, there is now a welfare loss; the expected utility of the representative agent has decreased:

$$Eu_2(w_2 + p - I(X)) + \lambda^{\text{SB}}(Eu_1(w_1 - p - X + I(X)) - v(a^{\text{SB}})) = w_2 + 187.73 \quad (12)$$

implying a welfare loss of 8.10 compared to the first best solution. We note that the premium p^{SB} here is lower than that for the full insurance case of the first best solution, owing to a smaller liability, by the endogenous contract design, for the insurer in the situation with moral hazard.

In the above example, we have used *the first-order approach*, justified in Jewitt [17].

Again, we see that deductibles may result, and also coinsurance above the deductible, when the classical model predicts full insurance and no deductible.

A slightly different point of view is the following: if the insured can gain by breaking the insurance contract, moral hazard is present. In such cases, the insurance company will often check that the terms of the insurance contract are being followed. Note that in the above model the insurance company *could not* observe the action a of the insured. This was precisely the cause of the problem in Example 2. Here, checking is possible, but will *cost money*, so it follows that the mere existence of moral hazard will lead to costs. These costs are different from the type of costs in Example 2, but of the same origin – moral hazard. The present situation clearly invites analysis as a two-person game played between the insurance company and its customer.

Borch [18] takes up this challenge, and finds a Nash equilibrium in mixed strategies. In this model, the insured pays the full cost of moral hazard through the premium.

It seems to have been Karl Borch's position that moral hazard ought to be met by imposing an extra premium.

From the above example, we note that increased premiums may not really be the point in dealing

with this problem: here we see that the second best premium p^{SB} is actually smaller than the first best premium p^{FB} . The important issue is that the contract creates incentives for the insured to protect his belongings, since he carries some of the risk himself under the second best risk-sharing rule. This is brought out very clearly in the above example, if the first best solution is implemented when moral hazard is present. Then the insured will set his level of effort $a = 0$, i.e., to its smallest possible level, since he has no incentive to avoid the loss, resulting in a very large loss with high probability (a singular situation with a Dirac distribution at infinity). Since the second best solution is the best when moral hazard is present, naturally this leads to a low profitability, in particular, for the insurer.

Conclusions

Optimal risk sharing was considered from the perspective of Pareto optimality. Relying on the concepts of a competitive equilibrium, Pareto optimality, Borch's Theorem, and the representative agent construction, we discussed some key results regarding risk tolerance and aggregation, which we applied to the problem of optimal risk sharing between an insurer and a customer. The development was motivated by a simple example, illustrating some of the finer points of this theory. It turned out that the concept of a Pareto optimal risk exchange is exactly the right notion of optimality in the present situation.

To explain deductibles, which do not readily follow from the neoclassical theory, we separately introduced (a) the insurable asset as a decision variable, (b) administrative costs, and (c) moral hazard, with the latter also illustrated by an example.

Optimal Stopping and Dynamic Programming

Brief History of Optimal Stopping

Optimal stopping problems originated in Wald's sequential analysis (see **Clinical Dose–Response Assessment**) [1], being a method of statistical inference (sequential probability ratio test) where the number of observations is not determined in advance of the experiment (see pp. 1–4 in the book for a historical account).

Snell [2] formulated a general optimal stopping problem for (discrete-time) stochastic processes, and using the methods suggested in the papers of Wald and Wolfowitz [3] and Arrow *et al.* [4], he characterized the solution by means of the smallest supermartingale (called *Snell's envelope*) dominating the gain (or reward) process. Studies in this direction (often referred to as *martingale methods*) (see **Insurance Pricing/Nonlife; Weather Derivatives; Mathematics of Risk and Reliability: A Select History**) are summarized in [5].

Dynkin [6] formulated a general optimal stopping problem for Markov processes and characterized the solution by means of the smallest superharmonic function dominating the gain function. Dynkin treated the case of discrete time in detail and indicated that the analogous results also hold in the case of continuous time. Studies in this direction (often referred to as *Markovian methods*) (see **Dependent Insurance Risks**) are summarized in [7, 8].

Formulation of Optimal Stopping Problem

Let $G = (G_t)$ be a stochastic process defined on a filtered probability space $(\Omega, \mathcal{F}, (\mathcal{F}_t), P)$. We interpret G_t as the *gain* (or *loss*) if the observation of G is stopped at time t , and we interpret $\mathcal{F}_t$ as the *information* available up to time t . It is assumed that G is *adapted* to the filtration $(\mathcal{F}_t)$ in the sense that each G_t is $\mathcal{F}_t$ measurable (i.e., the value G_t is known if $\mathcal{F}_t$ is known). Recall that each $\mathcal{F}_t$ is a σ algebra of subsets of Ω such that $\mathcal{F}_s \subseteq \mathcal{F}_t \subseteq \mathcal{F}$ for $s \leq t$. Typically, $(\mathcal{F}_t)$ coincides with the natural filtration (meaning that we know $\mathcal{F}_t$ if we know the sample path of G up to time t), but generally, it may also be larger. All our decisions in regard to optimal stopping at time t must be

based on the information $\mathcal{F}_t$ only (no anticipation is allowed).

The following definition formalizes the previous requirement and plays a key role in the study of optimal stopping.

Definition 1 A random variable τ defined on Ω and taking values in the time set is called a *stopping time* if the event $\{\tau \leq t\}$ belongs to $\mathcal{F}_t$ for all t .

Thus τ is a stopping time if (and only if) the information available up to time t is sufficient to determine (decide) whether τ is (or should be) smaller than or equal to t .

The *optimal stopping problem* seeks to solve

$$V = \sup_{0 \leq \tau \leq T} EG_\tau \quad (1)$$

where the supremum is taken over stopping times τ , and E denotes the expectation with respect to the measure P . Note that equation (1) involves two tasks: (a) to evaluate the *value function* V as explicitly as possible; (b) to exhibit an *optimal* stopping time τ_* at which the supremum is attained. The *horizon* T in equation (1) may be either *finite* or *infinite*. In the latter case, the value X_∞ needs to be specified (unless the supremum is taken only over stopping times τ that are finite valued). The most common practice is to set $G_\infty = \limsup_{t \rightarrow \infty} G_t$, but other choices are also possible. It is assumed throughout that $E \sup_t |G_t| < \infty$ so that EG_τ is well defined for every τ , but the former integrability condition can also be relaxed.

To solve the problem (1) in such a generality, one uses *martingale methods* mentioned following [2] above. Recall that a real-valued process $M = (M_t)$ defined on $(\Omega, \mathcal{F}, (\mathcal{F}_t), P)$ is a *martingale* if $E(M_t | \mathcal{F}_s) = M_s$ for all $s \leq t$, meaning that the predicted value for a future position of the process, given the entire past, equals the present position of the process. Recall also that the process $S = (S_t)$ defined on $(\Omega, \mathcal{F}, (\mathcal{F}_t), P)$ is a *supermartingale* if $E(S_t | \mathcal{F}_s) \leq S_s$ for all $s \leq t$, meaning that the predicted value for a future position of the process, given the entire past, is smaller than or equal to the present position of the process.

Very often, however, the problem (1) has a more specific structure where

$$G_t = G(X_t) \quad (2)$$

for some *time-homogeneous strong Markov process* $X = (X_t)$ taking values in a state space E and some real-valued (deterministic) function G on E .

Recall that X is a *Markov process* on $(\Omega, \mathcal{F}, (\mathcal{F}_t), P_x)$ if $P_x(X_t \in B | \mathcal{F}_s) = P_{X_s}(X_{t-s} \in B)$ for any measurable subset B of E and any $s \leq t$, meaning that the future states of the process, given the entire past, depend only on the present state of the process. Recall also that X is a *strong Markov process* if the deterministic t in the previous identity can be replaced by any stopping time τ (e.g., the first hitting time of X to a point or a set). Recall finally that X is said to be *time-homogeneous* if $P_x(X_t \in B | \mathcal{F}_s)$ does not depend on s and t but only on $t - s$ when $s \leq t$.

A profound step toward deeper understanding of the resulting problem (1) is to conduct its studies *via* functions of the initial point x of X in E , yielding the extended problem

$$V(x) = \sup_{0 \leq \tau \leq T} E_x G(X_\tau) \quad (3)$$

where E_x denotes the expectation with respect to the measure P_x under which the process X starts at x . This leads to *Markovian methods* mentioned following [6] above.

Solution to Optimal Stopping Problem

1. Consider the optimal stopping problem (1) when the time set $\{0, 1, \dots, N\}$ is discrete and the horizon $T = N$ is finite. Introduce the auxiliary problems

$$V_n = \sup_{n \leq \tau \leq N} E G_\tau \quad (4)$$

for $0 \leq n \leq N$ and note that $V_0 = V$. To solve the problem (1), one can let the time n go backward and proceed recursively as follows:

For $n = N$ we have to stop immediately and our gain S_N equals G_N . For $n = N - 1$ we can either stop or continue. If we stop, our gain S_{N-1} will be equal to G_{N-1} , and if we continue optimally, our gain S_{N-1} will be equal to $E(S_N | \mathcal{F}_{N-1})$. The latter conclusion reflects the fact that our decision about stopping or continuation at time $n = N - 1$ must be based on the information contained in $\mathcal{F}_{N-1}$ only. It follows that if $G_{N-1} \geq E(S_N | \mathcal{F}_{N-1})$, then we need to stop at time $n = N - 1$, and if $G_{N-1} < E(S_N | \mathcal{F}_{N-1})$ then we need to continue at time $n = N - 1$. For $n = N - 2, \dots, 0$, the considerations are continued analogously.

The method of *backward induction* just explained leads to a sequence of random variables $(S_n)_{0 \leq n \leq N}$ defined recursively as follows:

$$S_n = G_N \quad \text{for } n = N \quad (5)$$

$$S_n = \max \{G_n, E(S_{n+1} | \mathcal{F}_n)\} \quad \text{for } n = N - 1, \dots, 0 \quad (6)$$

The method also suggests considering optimality of the stopping time

$$\tau_n = \inf \{n \leq k \leq N : S_k = G_k\} \quad (7)$$

for $0 \leq n \leq N$. Note that the infimum in equation (7) is always attained.

The first part of the following theorem shows that S_n and τ_n solve the problem in a stochastic sense. The second part of the theorem shows that this leads to a solution of the initial problem (1). The third part of the theorem provides a supermartingale characterization of the solution. The method of backward induction and the results presented in the theorem play a central role in the theory of optimal stopping.

Theorem 1 *Consider the optimal stopping problem (4) for $0 \leq n \leq N$. Then we have:*

$$S_n \geq E(G_\tau | \mathcal{F}_n) \quad \text{for all } n \leq \tau \leq N \quad (8)$$

$$S_n = E(G_{\tau_n} | \mathcal{F}_n) \quad \text{for all } 0 \leq n \leq N \quad (9)$$

Moreover, if $0 \leq n \leq N$ is given and fixed, then we have:

The stopping time τ_n from equation (7) is optimal in equation (4) and $V_n = E S_n$ (10)

If τ_ is an optimal stopping time in equation (4),*

$$\text{then } \tau_n \leq \tau_* \text{ } P\text{-a.s.} \quad (11)$$

The sequence $(S_k)_{n \leq k \leq N}$ is the smallest

$$\text{supermartingale that dominates } (G_k)_{n \leq k \leq N} \quad (12)$$

The stopped sequence $(S_{k \wedge \tau_n})_{n \leq k \leq N}$

$$\text{is a martingale} \quad (13)$$

It follows from Theorem 1 that the optimal stopping problem (1) is solved inductively by solving the problems V_n for $n = N, N - 1, \dots, 0$. Moreover, the optimal stopping rule τ_n for V_n satisfies $\tau_n = \tau_k$ on

$\{\tau_n \geq k\}$ for $0 \leq n \leq k \leq N$, where τ_k is the optimal stopping rule for V_k . This, in other words, means that if it was not optimal to stop within the time set $\{n, n+1, \dots, k-1\}$, then the same optimality rule applies in the time set $\{k, k+1, \dots, N\}$. In particular, when specialized to the problem V_0 , the following general principle is obtained: if the stopping rule τ_0 is optimal for V_0 and it was not optimal to stop within the time set $\{0, 1, \dots, n-1\}$, then starting the observation at time n and based on the information $\mathcal{F}_n$, the same stopping rule is still optimal for the problem V_n . This principle of solution for optimal stopping problems has led to the general principle of *dynamic programming* (see **Repair, Inspection, and Replacement Models; Reliability Optimization**) (often referred to as *Bellman's principle*) in the theory of optimal stochastic control (see **Longevity Risk and Life Annuities; Stochastic Control for Insurance Companies; Repair, Inspection, and Replacement Models**) (see [9]).

The method of backward induction, by its nature, requires that the horizon N be finite so that the case of infinite horizon N remains uncovered. It turns out, however, that the random variables S_n defined by the recurrence relations (5) and (6) admit a different characterization that can be directly extended to the case of infinite horizon N . This characterization forms the basis for the second method that will now be discussed. With this aim, note that equations (10) and (11) in Theorem 1 suggest that $S_n = \sup_{n \leq \tau \leq N} E(G_\tau | \mathcal{F}_n)$ for all $0 \leq n \leq N$. A difficulty arises, however, from the fact that both equations (8) and (9) hold only P -a.s. so that the exceptional P -null set may depend on the given τ . Thus, if the supremum is taken over uncountably many τ , then the right-hand side need not define a measurable function, and the identity may fail as well. To overcome this difficulty, it turns out that the concept of *essential supremum* proves useful.

Recall that if $\{Z_\alpha : \alpha \in I\}$ is a family of random variables defined on $(\Omega, \mathcal{G}, P)$ where the index set I can be arbitrary, then there exists a countable subset J of I such that the random variable $Z^* : \Omega \rightarrow \overline{\mathbb{R}}$, defined by $Z^* = \sup_{\alpha \in J} Z_\alpha$ satisfies the following two properties: (a) $P(Z_\alpha \leq Z^*) = 1$ for each $\alpha \in I$ given and fixed; (b) If $\tilde{Z} : \Omega \rightarrow \overline{\mathbb{R}}$ is another random variable satisfying all the previous identities in place of Z^* , then $P(Z^* \leq \tilde{Z}) = 1$. The random variable Z^* is called the *essential supremum* of $\{Z_\alpha : \alpha \in I\}$

relative to P and is denoted by $Z^* = \text{ess sup}_{\alpha \in I} Z_\alpha$. It is determined by the properties (a) and (b) uniquely up to a P -null set.

With the concept of essential supremum, one can then rewrite equations (8) and (9) as follows:

$$S_n = \text{ess sup}_{n \leq \tau \leq N} E(G_\tau | \mathcal{F}_n) \quad (14)$$

for all $0 \leq n \leq N$. This identity provides an additional characterization of the sequence of random variables $(S_n)_{0 \leq n \leq N}$ introduced initially by means of the recurrence relations (5) and (6). Its advantage, in comparison with the recurrence relations, lies in the fact that the identity (14) can naturally be extended to the case of infinite horizon N . The results of this extension are analogous to the results of Theorem 1 (including equations (5) and (6)). [One may observe that the problem of finding S_n in equation (14) is no simpler than the problem of finding V_n in equation (4). The point is that the construction of S_n leads to a construction of the optimal stopping time in equation (7).]

Likewise, in the case of continuous-time set $[0, T]$, one extends equation (14) by setting

$$S_t = \text{ess sup}_{t \leq \tau \leq T} E(G_\tau | \mathcal{F}_t) \quad (15)$$

where the horizon T can be either finite or infinite. If the gain process G is right continuous and left continuous over stopping times, then the process $S = (S_t)$ admits a right-continuous modification and the results of Theorem 1 remain valid without major changes (it is also assumed that the filtration $(\mathcal{F}_t)$ is right continuous and that $\mathcal{F}_0$ contains all P -null sets in $\mathcal{F}$). Note that the analog of equation (12) then states that S is the smallest right-continuous supermartingale that dominates G . The process S is often referred to as the *Snell envelope* of G (both in discrete and continuous time).

2. Consider the optimal stopping problem (3) when the time set $\{0, 1, \dots, N\}$ is discrete and the horizon $T = N$ is finite. Introduce the auxiliary problems

$$V^{N-n}(x) = \sup_{0 \leq \tau \leq N-n} E_x G(X_\tau) \quad (16)$$

for $0 \leq n \leq N$ and note that $V^N(x) = V(x)$ for all x .

Since the problem (16) is equivalent to the problem (4), we can apply the method of backward induction equations (5) and (6) which lead to a

sequence of random variables $(S_n)_{0 \leq n \leq N}$ and a stopping time τ_n defined in equation (7). The key identity linking equation (16) to equation (4) is

$$S_n = V^{N-n}(X_n) \quad (17)$$

for $0 \leq n \leq N$, and the results of Theorem 1 are directly applicable. It follows that

$$\tau_0 = \inf\{0 \leq n \leq N : X_n \in D_n\} \quad (18)$$

where $D_n = \{x \in E : V^{N-n}(x) = G(x)\}$ for $0 \leq n \leq N$. Recall that the transition operator P_1 of X is defined by $P_1 F(x) = E_x F(X_1)$ for $x \in E$, whenever $F : E \rightarrow \mathbb{R}$ is a (bounded) measurable function.

Theorem 2 *Consider the optimal stopping problem (3) when the time set is discrete and the horizon is finite. Then the value function V^N solves the Wald–Bellman equation*

$$V^d(x) = \max\{G(x), P_1 V^{d-1}(x)\} \quad (19)$$

for $d = 1, \dots, N$ and $x \in E$ where $V^0 = G$. Moreover, we have:

The stopping time τ_0 from equation (18) is optimal in equation (3) (20)

If τ_ is an optimal stopping time in equation (3), then $\tau_0 \leq \tau_*$ P_x -a.s. for every $x \in E$* (21)

The sequence $(V^{N-n}(X_n))_{0 \leq n \leq N}$ is the smallest supermartingale that dominates $(G(X_n))_{0 \leq n \leq N}$ under P_x for every $x \in E$ (22)

The stopped sequence $(V^{N-n \wedge \tau_0}(X_{n \wedge \tau_0}))_{0 \leq n \leq N}$ is a martingale under P_x for every $x \in E$ (23)

The Wald–Bellman equation (19) can be written in a more compact form by setting $MF(x) = \max\{G(x), P_1 F(x)\}$ for $x \in E$ and noting that equation (19) reads $V^d(x) = M^d G(x)$ for $d = 0, 1, \dots, N$ where M^d denote the d -th power of M . These recurrence relations form a constructive method for finding $V = V^N$ when $\text{Law}(X_1|P_x)$ is known for $x \in E$.

The results of Theorem 2 extend to the case when the horizon $T = N$ is infinite without major changes. Noting that $N \mapsto V^N$ is increasing, it follows that $\lim_{N \rightarrow \infty} V^N$ exists and equals the

value function V , which solves the Wald–Bellman equation (19) with $V(x)$ in place of $V^d(x)$ and $V^{d-1}(x)$, respectively (when x is given and fixed). Moreover, it can be shown that if $x \mapsto \tilde{V}(x)$ is any (measurable) solution to this equation (satisfying also $E_x \sup_n \tilde{V}(X_n) < \infty$ for all x), then $V = \tilde{V}$ if and only if $\limsup_{n \rightarrow \infty} \tilde{V}(X_n) = \limsup_{n \rightarrow \infty} G(X_n)$ P_x -a.s. for all x . The optimal stopping time τ_0 from equation (18) is defined analogously by $\tau_D = \inf\{n \geq 0 : X_n \in D\}$ where $D = \{x \in E : V(x) = G(x)\}$.

3. To indicate how the results of Theorem 2 extend to the case of continuous-time set $[0, T]$, let us first note that if the horizon T is finite, then one needs to replace the process X_t by the process $Z_t = (t, X_t)$ so that the problem reads

$$V(t, x) = \sup_{0 \leq \tau \leq T-t} E_{t,x} G(t + \tau, X_{t+\tau}) \quad (24)$$

where the “rest of time” $T - t$ changes when the initial state $(t, x) \in [0, T] \times E$ changes in its first variable. It turns out, however, that no argument from the infinite horizon formulation is more seriously affected by this change, and the results will be identical if we simply think of a new process X to be Z , with a new “two-dimensional” state space E equal to $\mathbb{R}_+ \times E$. For these reasons, we will omit any reference to horizon in what follows.

Consider the optimal stopping problem (3) when the time set $[0, T]$ is continuous upon assuming that the following regularity conditions are satisfied: (a) E is a locally compact Hausdorff space with a countable base and the family of measurable sets equals the Borel σ -algebra on E ; (b) the sample paths of X are right continuous and left continuous over stopping times; and (c) the filtration $(\mathcal{F}_t)_{t \geq 0}$ is right continuous (implying that the first entry times to open and closed sets are stopping times) and that $\mathcal{F}_0$ contains all P -null sets from $\mathcal{F}$ (implying also that the first entry times to Borel sets are stopping times). Introduce the continuation set $C = \{x \in E : V(x) > G(x)\}$ and the stopping set $D = \{x \in E : V(x) = G(x)\}$. Define the first entry time τ_D of X into D by setting

$$\tau_D = \inf\{t : X_t \in D\} \quad (25)$$

The following definition plays a fundamental role in solving the optimal stopping problem (3). A

measurable function $F : E \rightarrow \mathbb{R}$ is said to be *superharmonic* if $E_x F(X_\tau) \leq F(x)$ for all stopping times τ and all $x \in E$. If F is lsc (lower semicontinuous) and $(F(X_t))_{t \geq 0}$ is uniformly integrable, then the following stochastic characterization of superharmonic functions is valid (recall equations (12) and (22)): F is superharmonic if and only if $(F(X_t))$ is a right-continuous supermartingale under P_x for every $x \in E$.

Theorem 3 *Consider the optimal stopping problem (3) when the time set is continuous, and suppose that the gain function G is continuous. Then we have:*

The stopping time τ_D from equation (25) is optimal in equation (3) (26)

If τ_ is an optimal stopping time in equation (3), then $\tau_D \leq \tau_*$ P_x -a.s. for every $x \in E$* (27)

The value function V is the smallest superharmonic function that dominates the gain function G on E (28)

The stopped sequence $(V(X_{t \wedge \tau_D}))$ is a martingale under P_x for every $x \in E$ (29)

The results of Theorem 3 remain valid if one assumes that G is finely continuous, and it can also be shown that this hypothesis implies that V is finely continuous. A function F is *finely continuous* (see [10], Chapter XI) if, roughly speaking, the process X sees F as continuous (even though F may be discontinuous). On the other hand, if X is a one-dimensional diffusion process, then V is continuous whenever G is measurable (see [8, p. 157]).

4. Theorem 3 shows that the optimal stopping problem (3) is equivalent to the problem of finding the smallest superharmonic function $\hat{V}$ that dominates G on E . Once $\hat{V}$ is found it follows that $\hat{V} = V$ and τ_D from equation (25) is optimal. This yields the following representation:

$$\hat{V}(x) = E_x G(X_{\tau_D}) \quad (30)$$

for the unknown function $\hat{V}$ and the unknown set D when $x \in E$. Because of the Markovian structure of X , any function of the form (30) is intimately related to a deterministic equation that governs X in mean (parabolic/elliptic *partial differential equations* when

X is continuous, or more general *partial integro-differential equations* when X has jumps).

To describe this connection, recall that the mean-value kinematics of the process X is described by the *characteristic operator* $\mathbb{L}_X$ defined on a function $F : E \rightarrow \mathbb{R}$ as follows:

$$\mathbb{L}_X F(x) = \lim_{U \downarrow x} \frac{E_x F(X_{\tau_{U^c}}) - F(x)}{E_x \tau_{U^c}} \quad (31)$$

where the limit is taken over a family of open sets U shrinking down to x in E . Under rather general conditions, it is possible to establish that the characteristic operator is an extension of the *infinitesimal operator* $\mathbb{L}_X$ defined as in equation (31) with deterministic t in place of random τ_{U^c} and with $t \downarrow 0$ in place of $U \downarrow x$ under the limit sign. Very often, one refers to $\mathbb{L}_X$ as the *infinitesimal generator* of the process X . Its infinitesimal role is uniquely determined through its action on sufficiently regular (smooth) functions F for which both limits in equation (31) exist and coincide. From general theory of Markov processes, one knows that (on a given relatively compact subset of E which is assumed to be $\mathbb{R}^d$) the infinitesimal generator $\mathbb{L}_X$ takes the following integro-differential form (cf. [11]):

$$\begin{aligned} \mathbb{L}_X F(x) = & \lambda(x)F(x) + \sum_{i=1}^d \rho_i(x) \frac{\partial F}{\partial x_i}(x) \\ & + \sum_{i,j=1}^d \sigma_{ij}(x) \frac{\partial^2 F}{\partial x_i \partial x_j}(x) \\ & + \int_{\mathbb{R}^d \setminus \{0\}} \left(F(y) - F(x) - \sum_{i=1}^d (y_i - x_i) \right. \\ & \times \left. \frac{\partial F}{\partial x_i}(x) \right) \nu(x, dy) \end{aligned} \quad (32)$$

where λ corresponds to killing (when negative) or creation (when positive), ρ is the drift coefficient, σ is the diffusion coefficient, and ν is the compensator of the measure μ of jumps of X . By the strong Markov property of X , it follows that any function $\hat{V}$ satisfying equation (30) solves the *Dirichlet problem*

$$\mathbb{L}_X \hat{V} = 0 \quad \text{in } C \quad (33)$$

$$\hat{V}|_D = G \quad (34)$$

Since the optimal stopping set D in this problem is unknown as well (making it a free-boundary

problem), the crucial question becomes to specify additional conditions that will single out the optimal stopping set D among all possible candidates.

5. The previous considerations lead to two traditional ways for finding $\widehat{V}$ when X and G are given: (a) *Wald–Bellman equation* and (b) *free-boundary problems*.

The book [7] provides numerous examples of (a), under various conditions on G and X . For example, it is known that if G is lsc and $E_x \inf_{t \geq 0} G(X_t) > -\infty$ for all $x \in E$, then $\widehat{V}$ can be computed as follows:

$$M_n G(x) := G(x) \vee E_x G(X_{1/2^n}) \quad (35)$$

$$\widehat{V}(x) = \lim_{n \rightarrow \infty} \lim_{N \rightarrow \infty} M_n^N G(x) \quad (36)$$

for $x \in E$, where M_n^N denotes the N -th power of M_n . The method of proof relies upon discretization of the time set $[0, T]$ and making use of discrete-time results reviewed above.

The book [8] presents various examples of (b). The basic idea is that $\widehat{V}$ and D should solve the free-boundary problem

$$\mathbb{L}_X \widehat{V} \leq 0 \quad (\widehat{V} \text{ minimal}) \quad (37)$$

$$\widehat{V} \geq G \quad (\widehat{V} > G \text{ on } C \ \& \ \widehat{V} = G \text{ on } D) \quad (38)$$

where $\mathbb{L}_X$ is the infinitesimal generator of X given by equation (32). Note that the inequality in equation (37) represents an analytic characterization of superharmonic functions.

The following “rule of thumb” specifies the additional conditions referred to following equations (33) and (34). If G is smooth and X after starting at ∂C (the boundary of C) enters $\text{int}(D)$ (the interior of D) immediately (e.g., when X is a diffusion process and ∂C is sufficiently nice), then the condition (37) (under equation (38)) splits into the two conditions

$$\mathbb{L}_X \widehat{V} = 0 \quad \text{in } C \quad (39)$$

$$\frac{\partial \widehat{V}}{\partial x} \Big|_{\partial C} = \frac{\partial G}{\partial x} \Big|_{\partial C} \quad (\text{smooth fit}) \quad (40)$$

On the other hand, if G is continuous and X after starting at ∂C does not enter $\text{int}(D)$ immediately (e.g., when X has jumps and no diffusion component, while ∂C may still be sufficiently nice) then the condition (37) (under equation (38)) splits into the two conditions

$$\mathbb{L}_X \widehat{V} = 0 \quad \text{in } C \quad (41)$$

$$\widehat{V} \Big|_{\partial C} = G \Big|_{\partial C} \quad (\text{continuous fit}) \quad (42)$$

A more precise meaning of these conditions is discussed in [8], Chapter IV.

The resulting free-boundary problems lead to a unique solution $\widehat{V}$ that coincides with the value function V . A powerful method for solving these problems consists in expressing V in terms of ∂C and then deriving a nonlinear (integral) equation for ∂C . Using *local time–space calculus* techniques, it is then possible to show that the latter equation characterizes ∂C uniquely in the class of admissible functions. For further details, see [8], Section 14 and the references therein.

6. The geometric interpretation of superharmonic functions (when X is a Brownian motion process) leads to an appealing physical interpretation of the value function V associated with the gain function G : if G depicts an obstacle, and a rope is put above G with both ends pulled to the ground, the resulting shape of the rope coincides with V (see Figure 1). Clearly, the fit of the rope and the obstacle should be smooth whenever the obstacle is smooth (smooth fit). A similar interpretation (as in Figure 1) extends to dimension two (membrane) and higher dimensions. This leads to a class of problems in mathematical physics called the “*obstacle problems*”.

Another class of problems coming from mathematical physics fits into the free-boundary setting above. These are processes of melting and solidification leading to the “*Stefan free-boundary problem*”. Imagine a chunk of ice (at temperature G) immersed in water (at temperature V). Then the ice–water interface (as a function of time and space) will coincide with the optimal boundary (surface)

Figure 1 An obstacle G and the rope V depicting the superharmonic characterization

∂C. The thermal energy transfer (heat) from water to ice follows the conservation of energy law and should happen smoothly (smooth fit). This illustrates a basic link between optimal stopping and the Stefan problem.

An Example of Optimal Stopping Problem

The book [8] presents various examples of optimal stopping problems arising from stochastic analysis (Chapter V), mathematical statistics (Chapter VI), mathematical finance (Chapter VII), and financial engineering (Chapter VIII). We conclude this exposition with one example that deals with *optimal prediction* and is closely related to the questions of *risk*.

Example 1 (Optimal prediction of the ultimate maximum) Imagine the real-line movement of a Brownian particle started at 0 during the time interval $[0, 1]$. Let S_1 denote the *maximal* positive height that the particle ever reaches during this time interval. As S_1 is a random quantity whose values depend on the *entire* Brownian path over the time interval, its *ultimate* value is unknown at any given time $t \in [0, 1]$. Following the Brownian particle from the initial time zero onward, the question arises, naturally, of how to determine a time when the movement should be terminated so that the position of the particle at that time is as “close” as possible to the *ultimate maximum* S_1 . In this example, we present the solution to this problem if “closeness” is measured by a mean-square distance.

To formulate the problem above more precisely, let $B = (B_t)_{0 \leq t \leq 1}$ be a standard Brownian motion, and let $(\mathcal{F}_t^B)_{0 \leq t \leq 1}$ denote the natural filtration generated by B . Setting $S_1 = \max_{0 \leq t \leq 1} B_t$, the optimal stopping/prediction problem is to find

$$V = \inf_{0 \leq \tau \leq 1} E(B_\tau - S_1)^2 \quad (43)$$

where the infimum is taken over all stopping times τ of B (i.e., with respect to $(\mathcal{F}_t^B)_{0 \leq t \leq 1}$). Note that the gain process in equation (43) depends on the future values of B as well.

The optimal stopping problem (43) is of interest, for example, in financial engineering, where an optimal decision (i.e., optimal stopping time) should be based on a prediction of the time when the observed process take its maximal value (over a given time interval). The argument also carries over to

many other applied problems where such predictions play a role.

It can be shown (see [12]) that the value V in equation (43) is given by the formula

$$V = 2\Phi(z_*) - 1 = 0.73 \dots \quad (44)$$

where $z_* = 1.12 \dots$ is the unique root to the equation $4\Phi(z_*) - 2z_*\varphi(z_*) - 3 = 0$, and the following stopping time is optimal:

$$\tau_* = \inf \left\{ 0 \leq t \leq 1 : S_t - B_t \geq z_* \sqrt{1-t} \right\} \quad (45)$$

where $S_t = \max_{0 \leq s \leq t} B_s$ for $0 \leq t \leq 1$. Recall that $\varphi(x) = (1/\sqrt{2\pi}) e^{-x^2/2}$ and $\Phi(x) = \int_{-\infty}^x \varphi(y) dy$ denote the density and distribution function of a standard normal variable.

It is interesting to note that

$$V_0 = \inf_{0 \leq t \leq 1} E(B_t - S_1)^2 = \frac{1}{\pi} + \frac{1}{2} = 0.81 \dots \quad (46)$$

with the infimum being attained at $t = 1/2$. Thus, by using the optimal stopping time (instead of an optimal deterministic time), *one makes savings of about 10% on average*.

The following identity holds (see [13]):

$$E|\tau - \theta| = E(B_\tau - B_\theta)^2 - \frac{1}{2} \quad (47)$$

for all stopping times τ of B satisfying $0 \leq \tau \leq 1$, where θ is the (P -a.s. unique) time at which the maximum of B on $[0, 1]$ is attained (i.e., $B_\theta = S_1$).

Taking the infimum on both sides of equation (47) over all stopping times τ of B satisfying $0 \leq \tau \leq 1$, we see that the stopping time τ_* given in equation (45) is optimal for both equation (43) as well as the optimal stopping/prediction problem

$$V_1 = \inf_{0 \leq \tau \leq 1} E|\tau - \theta| \quad (48)$$

where the infimum is taken over all stopping times τ of B . Thus, not only is τ_* the optimal time to stop *as close as possible to the ultimate maximum*, but also τ_* is the optimal time to stop *as close as possible to the time at which the ultimate maximum is attained*. This is indeed the most extraordinary feature of this particular stopping time. For further studies of optimal prediction problems, see [14, 15].

NICK H. BINGHAM AND GORAN PESKIR

Options and Guarantees in Life Insurance

A life insurance policy is a contract in which the policyholder pays premiums to the insurance company and, in return, the insurance company promises to pay benefits in the event of certain contingencies, for example, death or survival to retirement. The amount of the premiums and benefits may be fixed in advance or they may be variable. A key feature of these contracts is that the payment of the premiums and/or the benefits normally depends on whether the policyholder is alive or not. As the timing and amount of these payments is normally outside of the policyholder's control, the insurance company can take advantage of the law of large numbers through risk pooling in its determination of premiums (i.e., assuming that moral hazard is not present).

Many modern life insurance contracts often incorporate complex design features in the benefit structure that involve options and guarantees. These are of financial significance, and pricing, reserving, and risk management need to take into account the presence of these features.

Life insurance contracts can be classified on the basis of the interest rate offered to the policyholder, the associated guarantees, and the options contained in the benefit. Hence, we distinguish between the following types of contracts.

Unit-linked contract

The interest rate credited to the policyholder's account is linked directly and without time lags to the return on some reference portfolio (whose value is expressed in terms of units). In the case in which the reference portfolio is composed of equities only, the contract is described as equity linked.

Participating contract

The interest rate is calculated according to some smoothing surplus distribution mechanism. Examples include the conventional with profit contract, the accumulating with profit contract (now common in the United Kingdom), and the revalorization contract (common in Europe, excluding the United Kingdom). See Booth *et al.* [1] for more details.

Maturity guarantee

The contract promises to pay at least some absolute amount at maturity (for example, 80% of the initial premium).

Interest rate guarantee

The contract promises to credit the policyholder's account with some minimum return every period.

European-type life insurance contract

The embedded option(s) can be exercised only at maturity, which implies that the policyholder receives the benefit paid by the contract only at the end of its term.

American-type life insurance contract

The policy can, in this case, be terminated (exercised) at the policyholder's discretion (according to his/her circumstances) at any time during the life of the contract. In other words, the policyholder has an American-style option to sell back the policy to the issuing company any time he/she likes. This feature is known as a *surrender option*.

Participating Contracts with Minimum Guarantee

In its basic form, the contract comes into effect at time zero (i.e., the beginning of the first year) with the payment of a single premium, P_0 , from the policyholder to the insurance company (the extension to periodic premium is straightforward, but omitted owing to space constraints). The premiums is invested by the insurer in a fund, S , in the financial market together with the capital provided by the shareholders, E_0 , so that $P_0 = \theta S(0)$, $E_0 = (1 - \theta)S(0)$, where $S(0)$ is the initial value of the reference fund and θ is the cost allocation parameter.

The insurer commits to crediting interest to the policy's account balance according to a scheme linked to the annual returns on the fund until the contract expires. The benefit is payable if the policyholder dies during the policy term of T years, or (at maturity) after T years. In either event, the account is settled by a single payment from the insurance company to the policyholder, unless the policyholder is entitled to terminate the contract at his/her discretion prior to time T , through the surrender option.

This single payment is formed by a guaranteed component, P , which is generated by the cumulated interest credited during the term of the contract, and a discretionary bonus, B .

Guaranteed Benefit

At the beginning of each period, over the lifetime of the contract, the account P accumulates at rate r_P so that

$$\begin{cases} P(t) = P(t-1)(1 + r_P(t)) & t = 1, 2, \dots, T \\ P(0) = P_0 \end{cases} \quad (1)$$

The annual rate r_P at which the interest is credited usually includes a minimum-guaranteed rate, r_G , and a smoothed share of the annual returns generated by the reference fund, r_S . This latter component follows the fluctuations of the financial market; however, the presence of the guarantee imposes a floor limit on the level of the guaranteed benefit. In fact, if β denotes the so-called participation rate, then a common feature of $r_P(t)$ is

$$r_P(t) = \max\{r_G, \beta r_S(t)\}, \quad 0 \leq \beta < 1 \quad (2)$$

which can be rewritten as

$$r_P(t) = r_G + \max\{\beta r_S(t) - r_G, 0\} \quad (3)$$

On the one hand, equation (3) highlights the fact that the benefit is guaranteed never to fall below the contractually specified rate r_G ; hence, as mentioned above, the contract offers a downside protection to the policyholder, which is usually referred to in the literature as the risk-free bond element (see, for example Grosen and Jorgensen [2]). On the other hand, equation (3) also shows the presence of a European call option element in the design of the contract, which affects the risk features of the liabilities generated by the policy. Hence, special care has to be taken when reserving decisions are made.

The specification of the floating rate r_S varies from country to country. For example, in France, the balance P in the policyholder's account grows annually at the guaranteed rate, so that $\beta = 0$ (see, for example [3, 4]). In the United Kingdom, on the other hand, r_S may be calculated as the arithmetic

average of the returns on the reference fund over the last τ years

$$r_S(t) = \frac{1}{n} \left(\frac{S(t)}{S(t-1)} + \dots + \frac{S(t-n+1)}{S(t-n)} - n \right) \quad (4)$$

where n is the length of the smoothing period chosen as $n = \min(t, \tau)$. Alternatively, the floating rate in UK policies may be calculated using the “smoothed asset share” principle: let P^1 denote the “unsmoothed asset share” such that

$$P^1(t) = P^1(t-1)(1 + r_P(t)) \quad (5)$$

$$r_P(t) = \max \left\{ r_G, \beta \frac{S(t) - S(t-1)}{S(t-1)} \right\} \quad (6)$$

then the policy reserve is defined as the average of the value at time t of the unsmoothed asset share with weight α , and the value at time $(t-1)$ of the smoothed asset share, i.e., the policy reserve itself, with weight $(1 - \alpha)$. In other words,

$$P(t) = \alpha P^1(t) + (1 - \alpha)P(t-1) \quad (7)$$

with $\alpha \in (0, 1)$ playing the role of the smoothing parameter (see, for example, Ballotta [5] and Ballotta *et al.* [6] for further details). In Scandinavia, the policy design becomes more complex owing to the presence of a buffer mechanism aimed at stabilizing the annual net profit of the company. For example, in Denmark, insurance companies try to maintain the balance of the bonus account at a fixed, predetermined ratio (described by Grosen and Jorgensen [7] as the target buffer ratio) of the sum of the balances of the guaranteed benefit and the equity capital; consequently, the return on the policy depends on the excess return produced by the business over this target, i.e.,

$$r_S(t) = \frac{B(t-1)}{P(t-1) + E(t-1)} - \xi \quad (8)$$

where ξ is the fixed target buffer ratio.

Discretionary Bonus

Participating contracts usually offer, in addition to the guaranteed benefit, a discretionary bonus that depends on the surplus earned by the reference fund. In the United Kingdom, and in France, this additional benefit is called the *terminal bonus* (see **Value at**

Risk (VaR) and Risk Measures) or *participation bénéficiaire* (see Briys and de Varenne [3] and Ballotta *et al.* [6]); it is paid only at the expiration of the contract, and it is defined as

$$B(T) = \gamma(\theta S(T) - P(T))^+ \quad (9)$$

where γ is the so-called terminal bonus rate and denotes the percentage of the surplus distributed by the insurance company to the policyholders. The terminal bonus is therefore a European call option on the reference portfolio, capturing the fact that the surplus is distributed only when it is positive (i.e., the policyholders do not contribute to possible deficits of the insurance company). The terminal bonus may also be payable if the policyholder dies during the T year term.

In Scandinavia, the discretionary bonus has a form that is different from the above description. The account accumulates (i.e., is distributed) annually, and it provides a buffer mechanism that allows investment surplus to be set aside in years with good investment performance, to be used to cover the annual guarantee in years when the investment return is lower than the guaranteed rate, as described for example in Grosen and Jorgensen [2].

Default Option

The previous sections provided a general description of the overall benefit the participating policyholder is entitled to receive. However, if we assume the absence of an external guarantor, the company's promise can be honored only if the company is solvent at time T , i.e., if the insurer's assets are enough to provide the payment of the guaranteed benefit (that is $S(T) > P(T)$). If, instead, default occurs at maturity and the equityholders have limited liability, the policyholder takes only those assets that are available, while the equityholders are left with nothing. Thus, the liability, L , of the insurance company at maturity can be described as follows:

$$L(T) = \begin{cases} S(T) & \text{if } S(T) < P(T) \\ P(T) & \text{if } P(T) < S(T) < \frac{P(T)}{\theta} \\ P(T) + B(T) & \text{if } S(T) > \frac{P(T)}{\theta} \end{cases} \quad (10)$$

In a more compact way, we can write this as

$$L(T) = P(T) + B(T) - D(T) \quad (11)$$

where

$$D(T) = (P(T) - S(T))^+ \quad (12)$$

represents the payoff of the so-called default option. The default option is a European put option capturing the market loss that the policyholder suffers if a shortfall occurs and, as is described later on, it plays an important role in the valuation process of the insurance contract for the definition of appropriate premiums.

The supervisory authorities might impose more restrictive conditions and monitor the position of the insurance company regularly during the lifetime of the contract. In this case, if the market value of the assets is critically low during the lifetime of the contract, the regulatory authorities might decide to close down the company immediately and distribute the recovered wealth to stakeholders. A possible model for this situation of early default is provided, for example, by Grosen and Jorgensen [7] and Jorgensen [8].

Surrender Option

Insurance policies sometimes give the policyholder the right to terminate the contract prior to maturity and convert the future payments into an immediate cash payment. This feature is known as the *surrender option*, and the immediate cash payment is the so-called surrender value. To avoid financial losses, it is common practice for insurance companies to calculate the surrender value by applying an appropriate discount factor to the cumulated benefit, or mathematical reserve being held, at the time of termination.

The setting of the surrender conditions when designing a new insurance policy is crucial, especially when the financial component of the policy is predominant. The discount factor, in fact, could be fixed in such a way that the cash surrender values are penalizing; however, this might have non desirable effects on the marketability of the contract.

Other Options

Other optional features of life insurance contracts include the right to change the benefits, the premiums or the remaining duration of the policy without necessarily terminating it; the right to cease

premiums, but maintain the policy with an amended benefit level (the so-called paid-up option); the right to begin further insurance contracts without providing evidence of health (the so-called guaranteed insurability option).

Unit-Linked Contracts with Minimum Guarantee

In a unit-linked contract the benefit payable is directly related to the market value of the reference fund. A common feature is to include also a minimum guarantee $G(t)$, so that the benefit payable at time t (on death if $t < T$ or on maturity of $t = T$) is given by

$$P(t) = G(t) + \max [S(t) - G(t), 0] \quad (13)$$

$$= S(t) + \max [G(t) - S(t), 0] \quad (14)$$

which may thus be written as either a call option or a put option on $S(t)$.

Contracts with these features were common in the United Kingdom in the 1970s until the difficulties associated with the provision of these guarantees and in particular, the size of reserves needed were identified [9]. The financial-engineering approach to these embedded options was pioneered by Brennan and Schwartz [10], and Boyle and Schwartz [11]. These contracts remain common in the many markets and a full review of the literature is given by Hardy [12].

Guaranteed Annuity Options

A guaranteed annuity option (GAO) provides the policyholder the right to receive at retirement, at time T , either a cash benefit equal to the current value of the reference portfolio, $S(T)$, or an annuity which would be payable throughout his/her remaining lifetime and which is calculated at a guaranteed rate, g , depending on which has the greater value. This guarantee of the conversion rate between cash and pension income was a common feature of pension policies sold in the United Kingdom during the 1970s and 1980s.

Hence, if the policyholder is aged x_0 at time 0, when the contract is initiated, and N is the normal

retirement age, the GAO pays out at maturity $T = N - x_0$:

$$L(T) = (gS(T)a_{x_0+T} - S(T))^+ \quad (15)$$

$$= gS(T)(a_{x_0+T} - K)^+ \quad (16)$$

where $K = 1/g$ and a_{x_0+T} represents the “annuity factor”, i.e., the expected present value at time T of a life annuity which pays £1 per year throughout the remaining lifetime of the policyholder.

Other Insurance Contracts

Options and guarantees are implicit in many other types of insurance contracts. Thus, long-term contracts providing protection in the event of critical illness (for example, occurrence of a heart attack or incidence of cancer) may include a long-term guarantee regarding the definition of the medical conditions included. More details are provided by Booth *et al.* [1].

Pricing and Reserving

Following the recent developments in terms of accounting standards and capital requirements, insurance companies are required to mark-to-market the liabilities generated by the contracts sold to policyholders (*see Fair Value of Insurance Liabilities*). In the case of contracts containing minimum guarantees, and therefore embedded options, the market consistent pricing can be arrived at by following the theory of contingent claim valuation, and adopting the no-arbitrage principle. This implies that the premiums charged by the insurance company have to be fair when compared to the nominal value of the contract acquired by the policyholder in exchange for those premiums. Hence, for a policy offering a benefit at maturity T , the initial (single) premium P_0 paid by the policyholder has to satisfy the following

$$P_0 = \mathbb{E}^{\mathbb{Q}} [\tilde{L}(T)] \quad (17)$$

where $\mathbb{E}^{\mathbb{Q}}$ denotes the expectation calculated under the risk neutral probability $\mathbb{Q}$ (*see Risk-Neutral Pricing: Importance and Relevance*) and $\tilde{L}$ denotes the value of the overall liability due at maturity, discounted at the risk-free rate of interest. The rhs

of equation (17) represents the nominal market value of the insurance policy originating a liability $L(T)$ at time T ; consequently, if equation (17) is satisfied, the policyholder receives value for the money paid in the form of the actual premium, but at the same time, the insurer is not offering the benefits too cheaply, which would compromise the position of the equityholders.

From the point of view of the calculations, equation (17) can be solved once suitable assumptions are made for the model of the underlying risk drivers, like the reference portfolio and the term structure of interest rates. Further, the valuation framework has to be calibrated to the prevailing market conditions, to estimate the relevant parameters of the model (*see Nonparametric Calibration of Derivatives Models*).

Participating and Unit-Linked Contracts

The application of the market consistent pricing framework to the case of participating contracts with liability of the type described by equation (11) implies that the initial single premium has to satisfy the following condition

$$P_0 = V^P(0) + V^B(0) - V^D(0) \quad (18)$$

where

$$\begin{aligned} V^P(0) &= \mathbb{E}^Q [\tilde{P}(T)]; V^B(0) = \mathbb{E}^Q [\tilde{B}(T)]; \\ V^D(0) &= \mathbb{E}^Q [\tilde{D}(T)] \end{aligned} \quad (19)$$

Equation (18) can be rewritten as

$$P_0 + V^D(0) = V^P(0) + V^B(0) \quad (20)$$

from which it follows that the price of the default option, $V^D(0)$, represents an additional premium that the policyholder should pay to gain an “insurance” against a possible default of the company. In this sense, the default option premium can be interpreted as a safety loading, as discussed by Ballotta *et al.* [13].

A simple pricing formula for this type of life insurance contract is derived by Briys and de Varenne [3] for the case in which $\beta = 0$, as an application of the Black–Scholes option pricing formula. For more complex contract designs, though, the pricing

framework requires the implementation of suitable numerical algorithms, like for example, Monte Carlo simulation (*see Numerical Schemes for Stochastic Differential Equation Models*). The extension of the pricing framework to the case of a jump-diffusion economy (*see Lévy Processes in Asset Pricing*) has been covered by Ballotta [5].

The pricing of the surrender option, however, is a more complex problem. The surrender option is, in fact, an American-style contingent claim whose valuation relies on the application of optional stopping theory (*see Optimal Stopping and Dynamic Programming*). Examples of valuation framework for this part of the contract proposed in the literature make use of either the binomial tree model introduced by Cox *et al.* [14], or the “original” no-arbitrage approach of Black and Scholes [15] extended to incorporate the complex features of insurance contracts. Thus, under the first group of contributions, we mention the backward recursive valuation formulae developed by Bacinello [16] and Grosen and Jørgensen [2] for single premium participating contracts, Bacinello [17] for the case of contracts with annual premium, and Bacinello [18] for the case of unit-linked policies. The no-arbitrage argument has been instead adopted by Jensen *et al.* [19], who propose an approach to reduce the dimensionality of the problem to allow for the development and implementation of a finite difference algorithm for fast and accurate numerical evaluation of the contract. Finally, we cite Steffensen [20], who addresses the valuation problem of the surrender option as an application of the more general framework developed in this paper for intervention options. The value of the surrender part of the contract is hence obtained as the solution to a quasi-variational inequality, which generalizes the classical variational inequality used for the calculation of the price of American options.

A similar approach would be appropriate for unit-linked contracts with guarantees: see Jørgensen [12] for more details.

Guaranteed Annuity Options

The application of the market consistent pricing framework to the case of GAOs requires a stochastic model for the term structure of interest rates. Let r_t be the stochastic short rate of interest. Then, risk neutral valuation implies that the fair value at time T of the

annuity a_{x_0+T} can be calculated as

$$a_{x_0+T} = \mathbb{E}^{\mathbb{Q}} \left[\sum_{j=0}^{w-(T+x_0)} e^{-\int_T^{T_j} r_u du} 1_{(\tau_{x_0+T} > T_j - T)} \middle| \mathcal{F}_T \right] \quad (21)$$

where w is the largest survival age, T_j , $j = 1, \dots, w - (T + x_0)$, are the times of the annuity payments, $\mathcal{F}_T$ is the information flow at maturity and τ_y is a random variable representing the remaining lifetime of a policyholder aged y . Under the assumption of mortality independent of the market risk, it follows from equation (21) that

$$a_{x_0+T} = \sum_{j=0}^{w-(T+x)} {}_j p_{T+x} P(T, T + j) \quad (22)$$

where $P(t, \tau)$ is the price at time t of a zero-coupon bond with redemption date at τ , and ${}_j p_t$ is the survival probability. Equations (16) and (22) imply that the GAO can be seen as a call option written on a coupon-bearing bond, with coupons equal to the survival probabilities, and “coupon dates” $T < T + 1 < \dots < w - x$.

Pricing formulae for this contract have been derived under different market frameworks by Ballotta and Haberman [21], Boyle and Hardy [22], and Pelsser [23], among others. These contributions use fixed mortality tables to calculate the survival probabilities; possible extensions to the case of stochastic mortality have been proposed by Ballotta and Haberman [24] and Biffis and Millosovich [25].

Ordering of Insurance Risk

Comparing and ordering of risks is a basic problem of actuarial theory and practice. Risks are generally modeled by random variables or distribution functions. There is a great variety of stochastic models in use, which reflect the diversity of insurances like theft insurance, car insurance, liability insurance, etc. The diversity of insured population is reproduced in the stochastic models by introducing individual or collective risk models, which include internal, external, and group risk factors. There are risk models with rare extreme events and, on the other hand, models with moderate or even bounded risks. A particular problem in risk theory is dependence on a portfolio of insurance policies that may lead to a drastic increase in the risk of the portfolio.

Ordering of risks gives a guideline to many of the basic tasks of risk theory like measuring of risk or equivalent to the choice and analysis of risk premium principles (see **Risk Classification/Life; Equity-Linked Life Insurance**). It is also a basic tool for estimating the ruin probability (see **Individual Risk Models; Longevity Risk and Life Annuities; Ruin Theory**), the effect of various bonus–malus (see **Bonus–Malus Systems**) and credibility systems (see **Credibility Theory**), the confidence of statistical estimates forecasting the total of claims, etc. The ordering approach is an extension of the classical mean-variance approach of Markovitz to obtain a more specific analysis of essential risk features. Premium principles and risk measures should be consistent with reference to natural risk orderings.

In the following we shall concentrate on two of the most important orderings.

Stochastic Order and the Stop Loss Order

The basic question is, when does a risk X represent a riskier situation than another risk Y ? The answer to this question depends on the attitude toward risk aversion (see **Optimal Risk-Sharing and Deductibles in Insurance; Risk Attitude**). The most simple and obvious postulate is that stochastically larger risks describe more dangerous situations. Here, the

stochastic ordering $X \leq_{\text{st}} Y$ is defined by the postulate that the expectation of all increasing functions is larger for Y than for X , i.e.,

$$Ef(X) \leq Ef(Y) \quad \text{for all } f \in \mathcal{F} \quad (1)$$

where $\mathcal{F} = \mathcal{F}_i$ is the set of increasing functions. Equivalent to condition (1) is that the distribution functions F_X, F_Y of X, Y are comparable in the sense that

$$\begin{aligned} F_X(x) = P(X \leq x) &\geq P(Y \leq x) \\ &= F_Y(x) \end{aligned} \quad (2)$$

for all x . For most of the usual models in insurance it is not difficult to check whether $X \leq_{\text{st}} Y$. In particular, pointwise comparison of risks $X \leq Y$ implies stochastic ordering $X \leq_{\text{st}} Y$ (see Figures 1 and 2).

A common way to describe risk aversion behavior is in terms of utility functions (see **Mathematics of Risk and Reliability: A Select History; Risk Attitude; Clinical Dose–Response Assessment**). Risk X is preferred to risk Y by all risk averse agents (traders, persons) if inequality (equation (1)) holds true for all $f \in \mathcal{F} = \mathcal{F}_{\text{icx}}$, the class of increasing convex functions. In this case we write

$$X \leq_{\text{icx}} Y \quad \text{increasing convex order} \quad (3)$$

Increasing convex order combines the increase in stochastic order with an increase in the diffusiveness of risks. It is equivalently described by the comparison of the expectation of the angle (call) functions. For all real a

$$E(X - a)_+ \leq E(Y - a)_+ \quad (4)$$

i.e., the expected stop loss (see **Premium Calculation and Insurance Pricing; Risk Measures and Economic Capital for (Re)insurers**) risks are bigger for Y than for X . Therefore, stop loss contracts for the risk Y should have a higher premium than those for X . Equation (4) defines the *stop loss ordering*

$$X \leq_{\text{sl}} Y \quad (5)$$

The equivalence to the increasing convex order $\leq_{\text{icx}}$ is a basic justification for considering the stop loss order. For risks X, Y with the same expectation $EX = EY$ a sufficient condition for the stop loss

Figure 1 Stochastic ordering

Figure 2 Typical sample where $X \leq_{st} Y$; $\square : Y$; $\cdot : X$

Figure 3 Cut criterion

order in equation (5) is the Karlin–Novikov cut criterion saying that the distribution functions F_X, F_Y cross exactly one time, i.e., for some x_0

$$\begin{aligned} F_X(x) &\leq F_Y(x) \quad \text{for } x < x_0 \\ \text{and } F_X(x) &\geq F_Y(x) \quad \text{for } x > x_0 \end{aligned} \quad (6)$$

Inequality (6) is a consequence of twice crossing of the densities f_X, f_Y (see Figures 3 and 4).

Applications

Individual and Collective Risk Model

The classical individual model of risk theory has the form

$$X_{\text{ind}} = \sum_{i=1}^n b_i I_i \quad (7)$$

where $I_i \sim B(1, p_i)$ are independent Bernoulli distributed random variables. With probability p_i contract i will yield a claim of size $b_i \geq 0$ for any of the n policies. Replacing the claims $b_i I_i$ by $b_i N_i$ with Poisson-distributed $N_i \sim \text{Poisson}(\lambda_i)$ we obtain the classical approximation of the individual risk model by the collective model

$$X_{\text{coll}} = \sum_{i=1}^n b_i N_i \quad (8)$$

X_{coll} is called *collective model* since it has a representation of the form

$$X_{\text{coll}} = \sum_{i=1}^N X_i \quad (9)$$

with $N \sim \text{Poisson}(\lambda)$, $\lambda = \sum_{i=1}^n \lambda_i$ where (X_i) are independent and identically distributed with point masses $\frac{\lambda_i}{\lambda}$ at b_i , $1 \leq i \leq n$. If we choose $\lambda_i = p_i$, then the expected payments coincide; $EX_{\text{coll}} = EX_{\text{ind}}$ since $E I_i = p_i = E N_i$.

As an application of stochastic and stop loss ordering we get that the collective risk model X_{coll} leads to an overestimate of the risks and, therefore, also to an increase of the corresponding risk premiums for the whole portfolio

$$X_{\text{ind}} \leq_{sl} X_{\text{coll}} \quad (10)$$

From the cut criterion it follows that $I_i \leq_{sl} N_i$ and, therefore, by convolution stability of the stop loss order we obtain the comparison in equation (10). Choosing the parameter λ_i in the collective model as $\lambda_i = -\log(1 - p_i) > p_i$ we obtain a collective model, which is even more on the safe side for the insurer. With this choice, even stochastic ordering holds.

$$X_{ind} \leq_{st} X_{coll} \quad (11)$$

Reinsurance Contracts

As a second application of the stop loss ordering, we consider reinsurance contracts $I(X)$ for a risk X , where $0 \leq I(X) \leq X$ is the reinsured part of the risk X and $X - I(X)$ is the retained risk of the insurer. Consider the stop loss reinsurance contract $I_a(X) = (X - a)_+$, where a is chosen such that $E I_a(X) = E I(X)$. Then it follows from the cut criterion (equation (6)) that for any reinsurance contract $I(X)$

$$X - I_a(X) \leq_{sl} X - I(X) \quad (12)$$

holds, i.e., the stop loss contract $I_a(X)$ minimizes the retained risk of the insurer. Thus it is the *optimal reinsurance contract* for the insurer in the class of all contracts $I(X)$, which have the same expected risk.

Diversification of Risks

The stop loss ordering also gives a clue to the *diversification of risk* problem. Let $X_1, \dots, X_n$ be n independent and identically distributed risks. For any diversification strategy (p_i) , $0 \leq p_i$ with $\sum_{i=1}^n p_i = 1$, we obtain a diversified risk portfolio $\sum_{i=1}^n p_i X_i$ with p_i relative shares of the i th risk. Then by stochastic ordering techniques, it is easy to establish that under all diversification schemes (p_i) the *uniform diversification is optimal*, i.e., it has the lowest risk

$$\frac{1}{n} \sum_{i=1}^n X_i \leq_{sl} \sum_{i=1}^n p_i X_i \quad (13)$$

In fact, since the expectations of both sides in (equation (13)) coincide we even get the ordering in the stronger sense that equation (1) holds for $\mathcal{F} = \mathcal{F}_{cx}$, the *convex ordering*. Thus it also allows, in particular, comparison of the angle (put) function $(a - x)_+$.

Dependent Portfolios Increase Risk

The following example demonstrates the strong influence that dependence, between individual risks, may have on the risk of the joint portfolio (*see Dependent Insurance Risks*). Let $X_i = \Theta Y_i + (1 - \Theta) Z_i$, $1 \leq i \leq 10^5$, be a mixed model for a large portfolio with Bernoulli distributed $Y_i \sim B(1, \frac{1}{100})$, $Z_i \sim B(1, \frac{1}{1100})$, and $\Theta \sim B(1, \frac{1}{100})$, where all Θ, Y_i, Z_i are independent. It is easy to calculate that $X_i \sim B(1, \frac{1}{1000})$, i.e., each individual contract X_i yields a unit loss with small probability $\frac{1}{1000}$. The presence of Θ in the model implies an increase of the risk of all contracts (*positive dependence*) in rare cases. Thus typically, $\Theta = 0$ and the risks in the portfolio produce independently with small probability $\frac{1}{1100}$ a unit loss to the insurer. With small probability, however, a bad event $\Theta = 1$ happens, which causes all contracts to undergo an increase in risk, which now yields independently, with probability $\frac{1}{100}$, a unit loss for any of the contracts.

The common risk factor Θ introduces a small positive correlation of magnitude $\frac{1}{1000}$ between the individual risks. It is interesting to compare the total risk $T_n = \sum_{i=1}^n X_i$ in the mixed model (X_i) with the total risk $S_n = \sum_{i=1}^n W_i$ in an independent portfolio model (W_i), where $W_i \sim B(1, \frac{1}{1000})$ are distributed identically to X_i . Then, from stochastic ordering results as above, we obtain that the risk of T_n is bigger than that of S_n

$$S_n \leq_{sl} T_n \quad (14)$$

In fact, also $S_n \leq_{cx} T_n$ since $ES_n = ET_n = 100$. What is the magnitude of this difference? By the central limit theorem S_n is approximately normal distributed with mean $\mu = 100$ and dispersion $\sigma = 10$. Thus, $t = \mu + 5\sigma = 150$ is a *safe* retention limit for S_n . $P(S_n > t)$ is extremely small and the net premium is approximately

$$E(S_n - t)_+ \approx 2.8 \times 10^{-8} \quad (15)$$

The positive dependence in the mixed model (X_i), which is small in terms of correlation, causes a big increase of risk. For the mixed model we get, using the same retention limit t as in the independent model, the considerable stop loss premium

$$E(T_n - t)_+ \approx 8.5 \quad (16)$$

The presence of positive dependence in the mixed model implies that with probability about $\frac{1}{100}$, the

risk of the joint portfolio T_n is greater than 800. Thus, neglecting the common risk factor Θ and basing the calculation of premiums on the incorrect independent model (W_i) would lead to a disaster for the insurance company. The effect demonstrated in this example is present in a similar form in many related mixture models and clearly shows the necessity and importance of correct modeling of risks and also the necessity to use more advanced stochastic ordering tools going beyond mean-variance analysis.

An Outlook

Many further tools and orderings have been investigated in the literature to describe specific classes of risk models, how they compare with reference to different kinds of risk measures, and in which sense one distribution represents a more dangerous situation than another distribution. Several orderings have been developed for risk vectors or risk portfolios in particular, for measuring the degree of positive dependence in multivariate portfolios and its influence on various risk functionals. Important examples of positive dependence orderings are the supermodular, the directionally convex, the Δ -monotone orderings, and the positive orthant dependence orderings.

In various circumstances and for various risk measures results of the type, *more positive dependence implies higher risk* have been established.

A main actual topic of ordering of risks is to obtain sharp bounds on the risk based on partial knowledge of the dependence structure. For detailed exposition of ordering of insurance risks we refer the reader to the following references.

LUDGER RÜSCHENDORF

Parametric Probability Distributions in Reliability

In many applications of reliability theory and quantitative risk assessment, one is interested in random quantities for which one assumes a parametric probability distribution, as is generally often done in statistics and stochastics. In this paper, we briefly introduce some of the most commonly used parametric probability distributions in reliability, restricting ourselves to univariate random quantities and the most basic forms of the distributions. Far more detailed presentations of these distributions, with historical notes, discussions of properties and applications, and further generalizations, can be found in the *Wiley Encyclopedia of Statistical Sciences* [1]. Key text books in reliability and related topics tend to present these (and more) parametric probability distributions in greater detail, see e.g., Hougaard [2], Lawless [3], Martz and Waller [4], or Meeker and Escobar [5]. These main distributions are presented in a very brief manner in this article; they are used in many other articles in this encyclopedia, providing examples of their applications.

Parametric probability distributions are used both in stochastic analyses of reliability of systems, where they are mostly assumed to be fully known and corresponding properties of the system are analyzed, and in statistical inference, where process data are used to estimate the parameters of the distribution, often followed by a specific inference of interest. In the latter case, one must take care to also diagnose the assumptions underlying the specific parametric distribution assumed, to ensure a reasonable fit with the empirical data [1].

We present some main probability distributions for both continuous and discrete random quantities. For the former, parametric probability distributions can be uniquely specified via the probability density function (pdf) $f(t)$, the cumulative distribution function (cdf) $F(t)$, the survival function $S(t)$ (see **Insurance Applications of Life Tables; Risk Classification/Life; Mathematics of Risk and Reliability: A Select History**), or the hazard rate $h(t)$ (see **Mathematical Models of Credit Risk; Imprecise Reliability**). For example, for a nonnegative random quantity, as often used in reliability if one is interested in a random lifetime, these functions are related

as follows: $F(t) = \int_0^t f(u) du$, $S(t) = 1 - F(t)$ and $h(t) = f(t)/S(t)$. The hazard rate is often considered to be particularly attractive in reliability, as it represents an instantaneous rate of the occurrence of a failure, conditioned on no failure until now. For example, wear-out of a unit over time can be represented by an increasing hazard rate.

In the section titled “Normal and Related Distributions”, we briefly consider the normal distribution, and some related distributions, which, although important, play perhaps a lesser role in reliability than in other areas of application of statistics. In the section “Exponential and Related Distributions”, we present the exponential distribution, and the Weibull and gamma distributions, which are popular models in reliability and which can be considered as generalizations of the exponential distribution. The section titled “Distributions for Discrete Random Quantities” presents some important distributions for discrete random quantities; and in the section “Other Distributions”, some further important distributions for reliability are briefly mentioned. The paper concludes with some further remarks in the final section.

Normal and Related Distributions

The normal distribution (also known as the *Gaussian distribution*) is arguably the most important probability distribution in statistics, as it occurs as the limiting distribution when a sum of random quantities is considered (central limit theorem). In general, it also plays a big role in quantitative risk assessment, e.g., when risks of portfolios of investments are considered, but its role in reliability is somewhat less important. However, it is frequently used as a suitable probability distribution for the (natural) logarithm of a random lifetime, in which case the distribution of the lifetime is called *lognormal*. It is also related to the inverse Gaussian distribution (see **Lifetime Models and Risk Assessment**), which is of importance in some processes in reliability.

Normal Distribution

The normal distribution has two parameters, $-\infty < \mu < \infty$ and $\sigma^2 > 0$, which are equal to its mean and

variance, so its standard deviation is σ , and its pdf is

$$f(x|\mu, \sigma^2) = \frac{1}{(2\pi)^{1/2}\sigma} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right) \quad \text{for } -\infty < x < \infty \quad (1)$$

The cdf of the normal distribution is not available in closed form, so computations often used tables of the cdf of the standard normal distribution, which has $\mu = 0$ and $\sigma^2 = 1$, using the fact that $(X - \mu)/\sigma$ is standard normally distributed if X is normally distributed with parameters μ and σ^2 . Such tables are included in statistics text books, but all main statistical and mathematical software nowadays have good routines for the computation of the cdf of the normal distribution. Its direct use in reliability is often restricted to modeling residual or error terms in regression models, but it plays an important role as a model for log-transformed lifetimes.

Lognormal Distribution

A random quantity $T > 0$ is lognormally distributed if $X = \ln T$ has a normal distribution, so that $T = \exp(X)$ has pdf

$$f(t|\mu, \sigma^2) = \frac{1}{(2\pi)^{1/2}\sigma t} \exp\left(-\frac{(\ln t - \mu)^2}{2\sigma^2}\right) \quad \text{for } t > 0 \quad (2)$$

The mean and variance of T are $\exp(\mu + \sigma^2/2)$ and $[\exp(\sigma^2) - 1][\exp(2\mu + \sigma^2)]$, respectively. This distribution is quite popular as a model for lifetimes, even though its hazard rate has the somewhat unattractive property that it increases, from $h(0) = 0$, to a maximum, and thereafter decreases to 0 for $t \rightarrow \infty$. However, if attention is particularly directed toward early failure times, yet with a wear-out effect, then this model might be appropriate. One possible argument justifying the use of this model is related to the central limit theorem argument for the normal distribution. Informally stated, the latter implies that, if a random quantity can be considered to be the sum of many independent random quantities, then its distribution will be approximately normal. Hence, the same property holds for $\ln T$ if T has a lognormal distribution, with the log transform here meaning that T , for this argument, can be interpreted as the product of many independent random quantities, which might be attractive in certain types of failure processes. An

obvious argument for the popularity of the lognormal distribution was always the wide availability of statistical tables for the normal distribution, an argument that is less relevant nowadays.

Inverse Gaussian Distribution

Contrary to what the name might perhaps suggest, this is not a distribution for a simple transformation of a normally distributed random quantity. However, it becomes ever more important in reliability theory because of the fact that it is appropriate for stopping times in Brownian motion (*see Optimal Stopping and Dynamic Programming*) (“Gaussian”) processes, and these (and related) processes are playing an increasingly important role in reliability modeling. Suppose that a Brownian motion, starting at 0 at time $t = 0$, has drift $\psi \geq 0$ and variance σ^2 , then the time to reach the value $a > 0$ for the first time has an inverse Gaussian distribution with parameters $\beta = \frac{\psi}{2\sigma^2}$ and $\alpha = \frac{a}{\sigma\sqrt{2}}$. The pdf of this distribution is

$$f(t|\alpha, \beta) = \frac{\alpha \exp(2\alpha\beta^{1/2}) \exp(-\beta t - \alpha^2/t)}{\pi^{1/2} t^{3/2}} \quad \text{for } t > 0 \quad (3)$$

Padgett and Tomlinson [6] present an excellent example of the use of such processes to describe degradation, providing a model of continuous cumulative damage. They present a general accelerated test model in which failure times and degradation measures are combined for inference about system lifetime, with the drift of the process depending on the acceleration variable. Their paper includes an illustrative example using degradation data observed in carbon-film resistors.

Exponential and Related Distributions

The probability distributions in this section, for a continuous positive random quantity T , are very popular models for lifetimes, used in a wide variety of applications in reliability and beyond. We briefly introduce these distributions in basic forms, they can be generalized in a variety of ways. The most obvious generalization is inclusion of a location parameter τ , such that $T > \tau$, so effectively this shifts the start of the distribution from 0 to τ .

Mathematically, this is straightforward, but one must be careful in case of statistical inference based on the likelihood function, as for some models the maximum-likelihood estimator of τ is equal to the smallest observation in the available data, which is unreasonable from several perspectives.

Exponential Distribution

The exponential distribution has a constant hazard rate, say $h(t|\lambda) = \lambda > 0$, so its pdf is

$$f(t|\lambda) = \lambda \exp(-\lambda t) \quad \text{for } t > 0 \quad (4)$$

It is the unique model, for continuous T , with the so-called memory-less property, that is, the probability for the event to take place in a future interval does not depend on the current age of the item or individual considered. This distribution models the random times between events in homogeneous Poisson processes.

Weibull Distribution

The Weibull distribution is a very widely used probability distribution in reliability, and it has two parameters: scale parameter $\alpha > 0$ and shape parameter $\beta > 0$. It is easiest introduced *via* its hazard rate, which is

$$h(t|\alpha, \beta) = \alpha\beta(\alpha t)^{\beta-1} \quad \text{for } t > 0 \quad (5)$$

The corresponding survival function is

$$S(t|\alpha, \beta) = \exp(-(\alpha t)^\beta) \quad \text{for } t > 0 \quad (6)$$

For $\beta = 1$ this distribution is an exponential distribution, whereas $\beta > 1$ leads to an increasing hazard rate, and hence can be considered to model wear-out, as often deemed appropriate for mechanical units, and $\beta < 1$ leads to decreasing hazard rate, hence modeling wear-in of a product, as often advocated for electronic units. One Weibull distribution cannot model both wear-in and wear-out at different stages, e.g., it cannot resemble a “bath-tub shaped hazard rate”, but different Weibull distributions are often advocated for the different stages of a unit’s life. Although its form is mathematically straightforward, statistical inference based on the Weibull distribution is less trivial owing to the fact that there are no reduced-dimensional sufficient statistics for the shape

parameter β . This distribution is routinely available in standard mathematical and statistical software. The Weibull distribution with $\beta = 2$, hence with hazard rate a linear function of t , is also known as the *Rayleigh distribution*. Weibull distributions are also frequently used in regression-type inferences in reliability, enabling information from covariates to be taken into account. There is also a useful relationship between the Weibull distribution and an extreme value distribution (also called the *Gumbel distribution*), which occurs as a limiting distribution for extreme values of a sample, under some assumptions on the tail of the sample distribution: if T has a Weibull distribution, then $\ln T$ has such an extreme value distribution.

Gamma Distribution

The gamma distribution is also a useful lifetime model in many reliability applications, and has two parameters: scale parameter $\lambda > 0$ and shape parameter $\kappa > 0$. Its pdf is

$$f(t|\kappa, \lambda) = \frac{\lambda(\lambda t)^{\kappa-1} e^{-\lambda t}}{\Gamma(\kappa)} \quad \text{for } t > 0 \quad (7)$$

where $\Gamma(\kappa)$ is the gamma function, which of course equals the integral of the numerator of this pdf over $t > 0$. Computation of the cdf, survival function, and hazard rate is somewhat awkward as it involves the incomplete gamma function, yet this distribution is available in the leading mathematical and statistical software. The gamma distribution with $\kappa = 1$ is an exponential distribution, and gamma distributions with integer κ are also known as *Erlang distributions*. The pdf of the gamma distribution can have many different shapes, but it is not as commonly used in reliability as the Weibull distribution, possibly because of the lack of a clearly interpretable hazard rate. An attractive interpretation, however, occurs for integer κ , in which case a gamma distributed lifetime can be interpreted as the sum of κ independent exponentially distributed random quantities, which might, for example, be suitable if one wishes to model the lifetime of a system with spare units. This latter property also makes the gamma distribution popular in models for queuing systems. With increased popularity of Bayesian methods in statistics, the gamma distribution is used frequently as it is the conjugate prior distribution for both exponential and Poisson sampling distributions.

Distributions for Discrete Random Quantities

In reliability, as in many other application areas of stochastic modeling and statistical inference, one is also regularly interested in discrete random quantities, e.g., when counting the number of components that have performed a task successfully. The binomial distribution is probably the most frequently used distribution, whereas the negative binomial distribution and the Poisson distribution also deserve explicit mention. Of course, there are many variations and generalizations to these and other distributions for discrete random quantities; for these we refer again to the literature mentioned in the introductory paragraphs.

Binomial Distribution

Suppose that X denotes the number of successes in n independent trials, where each trial results either in a success with probability θ or in a failure with probability $1 - \theta$. The probability distribution of X , for a given value of n , is given by

$$P(X = x|\theta) = \binom{n}{x} \theta^x (1 - \theta)^{n-x} \quad \text{for } x \in \{0, 1, \dots, n\} \quad (8)$$

The expected value and variance of X are $n\theta$ and $n\theta(1 - \theta)$, respectively. Computation of these probabilities is straightforward if n is not too large, for large values of n two approximations can be used: for values of x close to 0 or n , the Poisson distribution with expected value $n\theta$ can be used as a reasonable approximation, whereas for other values of x an approximation based on the normal distribution, with the same expected value and variance is suitable. A standard “text-book” example for a situation where the binomial distribution is appropriate is n tosses of a possibly biased coin, where the coin lands heads up with probability θ on each toss, and where the number of tosses with heads up is counted. In situations where the possible outcomes are in more than two unordered categories, the multinomial distribution provides a suitable generalization of the binomial distribution [1].

Negative Binomial Distribution

The negative binomial distribution is a variation to the binomial distribution, with the total number of trials not a predetermined constant, but instead one counts the number of trials until a specified number of successes have occurred. Suppose again that trials are independent, each resulting either in a success with probability θ or a failure with probability $1 - \theta$, and let N denote the number of trials required to obtain the r th success. Then the probability distribution of N , for fixed r , is given by

$$P(N = n|\theta) = \binom{n-1}{r-1} \theta^r (1 - \theta)^{n-r} \quad \text{for } n = r, r+1, \dots \quad (9)$$

Sometimes the negative binomial distribution is defined slightly differently, that is, as counting the number of trials prior to the r th success. This distribution is important in its own right in probabilistic risk assessment, in reliability but also, for example, in quality control, but it is also increasingly used in Bayesian statistical inferences [4], as it occurs as the posterior predictive distribution for Poisson sampling with a conjugate gamma prior distribution. The special case of $r = 1$ is known as the *geometric distribution*, which simply counts the number of trials until the first success has occurred.

Poisson Distribution

A random quantity X has a Poisson distribution with expected value μ if its probability distribution is given by

$$P(X = x|\mu) = \frac{e^{-\mu} \mu^x}{x!} \quad \text{for } x = 0, 1, 2, \dots \quad (10)$$

This distribution is particularly important in stochastic processes, where it counts the number of events in a given period of time. For example, for a nonhomogeneous Poisson process with failure rate function $\lambda(t)$, the number of events in time interval $[t_1, t_2]$ has a Poisson distribution with expected value $\mu = \int_{t_1}^{t_2} \lambda(u) du$.

Other Distributions

Many other parametric probability distributions play an important role in some specific reliability applications. We briefly mention some of them, but refer to

the literature, e.g., the sources mentioned in the introductory paragraphs, for more details. Historically, the log-logistic distribution (*see* **Lifetime Models and Risk Assessment**) was frequently used in reliability, with a lifetime T having a log-logistic distribution if $Y = \ln T$ has a logistic distribution with pdf

$$f(y|\mu, \sigma) = \frac{\exp[(y - \mu)/\sigma]}{\sigma(1 + \exp[(y - \mu)/\sigma])^2} \quad \text{for } -\infty < y < \infty \quad (11)$$

with parameters $-\infty < \mu < \infty$ and $\sigma > 0$. This distribution is very similar to the normal distribution, but its survival function is available in closed form and hence it makes it easier to deal with right-censored observations, which often occur in reliability applications.

The uniform distribution, which has a constant pdf over a finite interval, is also useful in some reliability applications. For example, it models the times of events in a homogeneous Poisson process (*see* **Product Risk Management: Testing and Warranties; Reliability Growth Testing**) if the total number of events over a time interval of predetermined length is given. It is also frequently used in Bayesian statistics, as a prior distribution which, as is sometimes argued, can reflect quite limited prior knowledge being available. The beta distribution is also popular in Bayesian statistics, as it is a conjugate prior for binomial sampling models.

The Gompertz distribution is characterized by an attractive form for the hazard rate, given by $h(t) = \lambda\phi^t$ for $t > 0$, with scale parameter $\lambda > 0$ and shape parameter $\phi > 0$. Clearly, $\phi = 1$ gives the Exponential distribution, $\phi > 1$ models an increasing hazard rate (and hence can be used to model wear-out), but for $\phi < 1$, so decreasing hazard rate (“wear-in”), a problem occurs as the corresponding probability distribution is improper (i.e., its density does not integrate to 1 for $t > 0$). This latter aspect could be interpreted as if a proportion of the population considered cannot experience the event of interest. We mention this distribution mostly due to its apparently attractive hazard rate, and to emphasize the complications that can occur already with such rather simple mathematical forms. The Gompertz distribution has been used in actuarial mathematics since the early 19th century.

When we presented the Weibull distribution in the section “Exponential and Related Distributions”, we

briefly referred to an extreme value distribution. Generally, there are several extreme value distributions (three main functional forms), which occur for the maximum (or minimum) of n identically distributed real-valued random quantities if $n \rightarrow \infty$, and which often provide good approximations for the distribution of this maximum (or minimum) if n is large. These distributions are useful in a variety of reliability applications, for example, those related to reliability of systems or to structural reliability and overloads.

In this paper, we have restricted attention to univariate random quantities. Of course, in many reliability applications one is interested in multivariate random quantities, we refer to Hougaard [2] for an excellent presentation of related statistical theory, including useful parametric distributions for multivariate data.

Concluding Remarks

Basic parametric probability distributions, such as those presented in this paper, are also often used as part of more complex statistical models, such as mixture models, Bayesian hierarchical models, models with covariates or parametric models for processes. We refer the reader to the literature (*see* the introductory paragraphs of this article) for further discussion of such models; several examples are provided in other articles in this encyclopedia. Parametric models are certainly not always suitable. In particular, if one has many data available the use of nonparametric or semiparametric methods might be preferable because of their increased flexibility to adapt to specific features of the data. With increased computational power, applications of non- and semiparametric methods have become more widely available, yet parametric distributions are likely to remain important tools in reliability and risk assessment.

It is often an advantage if the parameters have an intuitive interpretation. Several of the parametric probability distributions discussed in this paper, including normal, exponential and gamma (but unfortunately not the Weibull distribution, unless its shape parameter is assumed to be a known constant), belong to the so-called exponential family of distributions [7], for which the parameters can be related to one- or two-dimensional sufficient statistics that summarize the data; this has the added benefit of available

conjugate priors to simplify computation in Bayesian statistics.

When choosing a parametric distribution as a model in a specific application, one often has to look for a suitable balance between simplicity of the model and corresponding computational aspects, and how flexible and realistic the model is. As mentioned before, for trustworthiness of statistical inferences based on an assumed parametric model, it is important that the choice of the model is well explained and, wherever possible, diagnostic methods (e.g., “goodness-of-fit tests” [1]) are used to check whether the model fits well with the available data.

FRANK P.A. COOLEN

Persistent Organic Pollutants

Widespread concern about persistent organic pollutants (POPs) dawned with the demonstration that the organochlorine pesticide Dichloro-diphenyl-trichloro-ethane (DDT) was causing widespread reproductive failures among fish-eating birds in the 1960s and 1970s [1, 2]. The endocrine-disrupting properties of DDT and its metabolites caused eggshell thinning, and nesting females crushed their unwitting offspring before they had a chance to hatch [3, 4].

This fundamental lesson in wildlife toxicology launched a rocky start along a path that would scrutinize and eventually regulate chemicals possessing three fundamental properties: those which are persistent, bioaccumulative, and toxic (PBT). Hence the catchall term *POP* amalgamated a wide group of chemicals for the purposes of scientific investigation, risk assessment, management scrutiny, and regulation. The extent to which individual POPs are deemed also to be “PBT” represents the basis for their regulation and inclusion in international treaties.

The Persistent Organic Pollutants (POPs)

It is important to first review some of the basic features of the POPs. POPs include such notable members as the *polychlorinated biphenyls* (PCBs) (see **Polychlorinated Biphenyls**), *dioxins* (see **Health Hazards Posed by Dioxin**) (polychlorinated dibenzo-*p*-dioxins (PCDDs)), furans (polychlorinated dibenzofurans (PCDFs)), organochlorine pesticides, and polybrominated diphenyl ethers (PBDEs). While small quantities of dioxins and furans originate from natural sources including forest fires and volcanoes, the spatial and temporal trends in the levels of these contaminants reveal human activities to dominate their release into the biosphere. PCBs and organochlorine pesticides have no known natural sources. POPs of anthropogenic origin are either produced intentionally (e.g., PCBs, organochlorine pesticides) or represent unintentional by-products of processes (e.g., dioxins and furans resulting from incomplete combustion, pulp kraft bleaching, or pesticide manufacture). Some are or were produced for “closed” or partially closed applications (e.g.,

PCBs as dielectric fluids), while others are or were produced for intentional application to the environment (e.g., pesticide application to crops). The physicochemical characteristics of the POPs underlie much of the current concerns about regulation, transport/fate, and effects (see Table 1).

POPs are persistent, as evidenced from long air, water, or soil half-lives, and resistance to photolytic or microbial breakdown [10, 11]. This feature has bearing on the ecological risks associated with POPs, since any release of POPs to the environment can lead to long-term local or global concerns (see **Ecological Risk Assessment**). This also has bearing on remediation measures should site-specific cleanups be instigated, as special measures must be employed to reduce the risks of further environmental contamination (e.g., sediment capping, landfill) or to destroy the chemicals in question (e.g., high-temperature incineration at specialized facilities and/or the use of specialized bacteria capable of breaking down the product). While POPs mobilized from a source or application are generally “beyond” management, site-specific remediation strategies have been partially successful at facilitating degradation of some parent POPs [12–15].

POPs are bioaccumulative, as evidenced by their accumulation in organisms, their magnification with increasing trophic levels in aquatic food webs, and their resistance to metabolic elimination in biota. This feature represents perhaps the most pressing concern from a risk assessment perspective. Fish-eating wildlife including seabirds and marine mammals are particularly vulnerable to contamination, becoming highly contaminated in such industrial regions as the St Lawrence estuary in Quebec, Canada [16, 17], the Baltic Sea in northern Europe [18, 19], and coastal California in the United States [20, 21]. Certain human consumer groups that rely heavily on seafoods have also been found to be more contaminated than their supermarket-oriented counterparts [22–24], a finding that drew home concerns about risk that had previously been seen to be largely an ecological issue. POPs emerged as a human concern, changing the nature of the perception, the risk, and the risk paradigm.

POPs are toxic, in that members can disrupt endocrine (hormone) systems and alter the growth and development of skeletal, reproductive, neurological, and immune systems. While adverse effects

2 Persistent Organic Pollutants

Table 1 The physicochemical properties of the persistent organic pollutants (POPs) serve to guide regulatory scrutiny. Of these POPs twelve have been targeted for international action under the terms of the Stockholm Convention, while others remain as “candidates” for possible inclusion. The discovery of many of these POPs in remote regions raised concerns about possible health effects in human and wildlife^(a)

	Common name	Use	Log K_{ow}	Molecular weight
Stockholm POPs	Aldrin	Insecticide; seed treatment	5.17–7.4 ^(b)	364.92
	Chlordane	Insecticide; earthworm control	6.00 ^(b)	409.78
	DDT	Insecticide – primarily for malaria control	4.89–6.914 ^(b)	354.49
	Dieldrin	Insecticide	3.692–6.2 ^(b)	380.91
	Dioxins	By-product of manufacturing/combustion	4.75–8.20 ^(c)	218.5–460.0
	Furans	By-product of manufacturing/combustion	5.44–8.0 ^(c)	237.1–443.8
	Endrin	Insecticide; rodenticide	5.2 ^(d)	380.92
	HCB	Pesticide; by-product	5.73 ^(d)	284.78
	Heptachlor	Insecticide; earthworm control	4.40–5.5 ^(b)	373.32
	Mirex	Insecticide; fire retardant	5.28 ^(d)	545.5
	PCBs	Dielectric fluids	4.3–8.26 ^(c)	188.7–498.7
	Toxaphene	Pesticide; control of scabies	3.23–5.50 ^(b)	413.82
Candidate POPs	Chlordecone	Insecticide	5.41 ^(d)	490.6
	HCH	Insecticide; wood treatment	3.72 ^(d)	290.8
	PCP	Biocide; wood preservative	5.12 ^(d)	266.34
	Endosulfan	Insecticide	3.83 ^(d)	406.93
	HCBD	Pesticide; by-product	4.78 ^(d)	260.76
	Dicofol	Pesticide	4.28 ^(d)	370.47
	Methoxychlor	Insecticide; biocide	5.08 ^(d)	345.65
	HBCD	Brominated flame retardant	5.645 ^(d)	631.69
	BDEs			
	Penta-BDE	Brominated flame retardant	6.53–6.76 ^(e)	564.7
	Octa-BDE	Brominated flame retardant	7.90 ^(e)	801.47

have been noted in several high-profile accidental poisonings of humans [25–27], the widespread exposure of all humans to low-to-moderate levels of POPs in their diet represents a more insidious challenge to risk assessors and managers. Adverse health effects, including small-for-gestational-age, immune function deficiencies, altered thyroid hormone levels, and impaired neurological development, have been documented in Dutch infants in a long-term study of average (i.e., not belonging to a cohort of concern) citizens [28, 29].

A number of similar health effects noted in contaminated wildlife populations not only provided an epidemiological basis for “real-world” interpretation, but also initiated widespread concerns about possible human health implications. The “human–wildlife” connection was born [30, 31]. In both cases, however, causal linkages were lacking, a feature that led to numerous mechanistic studies of laboratory animals wherein single-chemical, dose–response experiments provided insight into mechanisms of action for different chemicals, evaluated the relative potencies of different chemicals with similar structures (e.g., the toxic equivalency quotient (TEQ) for dioxin-like PCBs, PCDDs and PCDFs, or TEQ) [32], and provided a basis for extrapolation among species.

Many of the concerns about POP-associated toxic risk to humans originated as a result of the studies of wildlife. Associations between POP levels and adverse health effects in seabirds and marine mammals have been described in many industrial regions. Reproductive impairment in Baltic seals, St Lawrence belugas and California sea lions has been described during peak DDT and PCB use in the 1960 and

1970s [33–35]. The onset of skeletal abnormalities in Baltic seal populations after World War II [36], and the appearance of multifaceted abnormalities in Great Lakes fish-eating birds [37, 38], indicated a disruption of developmental processes. Mass mortalities associated with the introduction of new pathogens into vulnerable populations of seals inhabiting contaminated industrial regions are thought to be in part due to a contaminant-related reduction in the effectiveness of their immune systems to disease [39, 40]. Two major captive feeding studies of harbor seals have contributed to a more controlled assessment of POP effects, wherein a contaminated diet of fish reduced reproductive performance, and caused immunotoxicity and endocrine disruption [39, 41–43].

While the “PBT” characteristics largely shape the nature of the movement, fate, and effects of POPs in the environment, one additional feature is considered under the terms of the United Nations Environment Programme (UNEP) sponsored Stockholm Convention. This includes the “potential for long-range environmental transport”. Meeting this criterion involves demonstrating that a chemical is found in remote environments and that it was introduced to that environment *via* air, water, or biological transport. These characteristics of POPs make containment at local hotspots very difficult, and allow for escape *via* volatilization, movement with river or ocean currents, or export *via* migrating wildlife to take place. When one looks, one finds that chemicals of virtually all POP classes have been detected in remote parts of the world. Perhaps the more pressing concerns are the levels to which they accumulate, their behavior in remote food webs, their persistence

in the environment in question, and their toxicity to biota.

Transport, Fate, and Effects of POPs in the Environment

Individual POPs vary in the way in which they behave within each of the four above categories, and hence in the way in which they meet or fail to meet, the criteria set by national and international regulatory bodies. A brief summary of the salient scientific features of POPs as they enter and move through the environment, preferentially accumulate in certain species, and affect the health of organisms will help to shed light upon the links between scientific observations, risk assessments, and regulatory requirements.

POPs are fat soluble, and hence do not dissolve readily in water, but preferentially partition into lipid and organic components of the environment. Since this partitioning represents a relationship between the properties of the chemical in question and the properties of the environmental matrix within which it finds itself, partitioning coefficients have become useful proxies for the behavior of chemicals in the environment, and have greatly facilitated risk assessments at multiple levels (from design and manufacture to regulatory scrutiny to site-specific risk assessments). The partitioning of POPs between air, water, and organic phases are described by the partitioning coefficients for octanol/water (K_{ow}), octanol/air (K_{oa}), and air/water (K_{aw}).

Chemicals with higher $K_{o/w}$ values dissolve more readily in lipids, thereby driving accumulation in biota. However, an “optimal range” exists, where by those POPs falling between Log $K_{o/w}$ values of ~ 5.8 – 7.5 preferentially accumulate in aquatic organisms (see Figure 1a and b). The importance of lipids in determining the magnification of POPs in aquatic food webs is further demonstrated through correlations between POP concentrations and stable nitrogen isotopes (^{15}N : ^{14}N) measured in tissues of different species (see Figure 2; food web). With increasing trophic level, nitrogen isotopes fractionate toward a heavier signature, while POP concentrations increase.

The dispersion of POPs away from source *via* air, water, or biological transport also varies as a function of their physicochemical properties, as evidenced by fractionation as one moves away from the sites

of industrial activities into remote sites. Increasingly “light” PCB and POP signatures have been observed in lake sediments [47], burbot (*Lota lota*) [48], frogs (*Rana temporaria*) [49], and harbor seals (*Phoca vitulina*) [50] along latitudinal gradients. Altitude also influences POP patterns, with a temperature-related condensation and deposition at upper elevations [51], preferentially delivering some of the “lighter” POPs to biota [52, 53]. Moving air masses can readily transport POPs to remote sites in a matter of days, but slow-moving ocean currents and pulsating biological migrations also represent increasingly important modes of transport for POPs [54, 55]. The distillation of POPs in a global context leads to a fractionation that is contingent upon their chemical properties; this process is sometimes referred to as the *grasshopper effect* (see Figure 3) [56].

And while preferential accumulation indeed must reflect the degree to which a given chemical is “lipophilic”, its resistance to metabolic attack is also a requisite feature for magnification in aquatic food webs. Detoxification enzymes in biota possess the ability to eliminate parent POPs through the actions of the cytochrome P450 superfamily of enzymes, processes that lead to the formation of water-soluble, hydroxyl- and methyl-sulfonyl metabolites [57]. Metabolism may therefore be considered as an important driver of POP “patterns” in aquatic food webs, with an increasing dominance of persistent congeners with increasing trophic level, and the consequent loss of more metabolizable congeners [58].

The resemblance between many POPs and natural hormones underlies concerns about the potential for adverse health effects in humans and wildlife. By interacting with natural hormone receptors in biota, POPs can disrupt endocrine processes and influence the growth, development, and maintenance of organ systems. Carefully controlled, single-chemical, dose-response experiments using laboratory animals of cell-based studies have provided a mechanistic understanding of the effects of many individual POPs. Such certainty is not generally available for humans and wildlife, something that has required alternative study designs or approaches. While complex mixtures of POPs complicate a mechanistic interpretation of the “causal” chemical, a “weight of evidence” approach has been applied to evaluate POP risks and identify specific chemical classes of concern, such as the PCBs and DDT [33, 59, 60].

Figure 1 Persistent organic pollutants (POPs) amplify in food webs, but the extent to which this takes place varies as a function of their octanol–water partitioning coefficient ($\log K_{o/w}$). (a) Biomagnification factors (BMFs) for different POPs (including PCB congeners) in trout [Reproduced from [45]. © American Chemical Society, 2005.] (b) The delivery of different POPs from Pacific salmon to British Columbia grizzly bears is shaped by the $\log K_{o/w}$ of different POPs, (open circles: organochlorine pesticides; closed circles: PCB congeners; triangles: PBDE congeners) with an optimal range of 5.8–7.5 [Reproduced from [46]. © American Chemical Society, 2001.]

Figure 2 One of the fundamental features of persistent organic pollutants (POPs) is their tendency to biomagnify in aquatic food webs. The relationship observed between the recalcitrant PCB 180 and trophic position in an Arctic food web underscores this feature, and points to the potential for health risks at the top of the food web [46]. (Closed circles: pelagic zooplankton; open circles: benthic amphipods; triangles: Arctic cod; open squares: ringed seals; closed squares: seabirds. Acronyms: DOVE: dovekie; TBMU: thick-billed murre; BLGU: black guillemot; IVGU: ivory gull; GLGU: glaucous gull; NOFU: northern fulmar) [Reproduced from [46]. © American Chemical Society, 2001.]

Figure 3 The movement of persistent organic pollutants away from source is governed by the interaction between their physicochemical properties and environmental matrices. The “grasshopper effect” refers to the movement of POPs into remote, typically colder, regions of the world, with a fractionation process along the way shaping the chemical signature. Altitudinal gradients have also been observed, reflecting a cold condensation at higher elevations

Assessing POP Risks: Past, Present, and Future

Every reach of the world has become contaminated with POPs. Remote food webs in alpine lakes, boreal wetlands, polar oceans, and isolated coastal environments are contaminated with POPs as a result of the persistence of these contaminants, their tendency to move large distances, and their attraction to lipids. The degree to which the widespread dispersion of POPs and subsequent contamination of aquatic food webs has impacted the health of humans and wildlife remains a fundamental concern [61, 62]. Observations of reduced immune function in breast-fed Inuit infants, impaired neurological development in infants born to sportfishing families, and endocrine disruption in seabirds and polar bears in the Arctic indicate that POPs threaten the health and viability of populations that are far removed from the origin of the chemicals [63–66].

The protection of humans and wildlife from the unwanted effects of POPs represents a daunting challenge for risk assessors, managers, and regulators. The cumulative evidence from common POP effects in humans and wildlife [67] was used as an example in support of a proposed integrated human and ecological risk assessment framework [68]. Such an example can serve as a form of “forensic” risk assessment that documents past regulatory failures, or can help to guide site-specific remediation efforts, or can contribute to new and improved paradigms for chemical design, regulation, and/or use. The extent to which such a framework could prove effective in preventing future failures remains to be evaluated.

The development and adoption of the Stockholm Convention reflect, in part, the recognition that POPs know no national boundaries, are readily transported to distant reaches, amplify in food webs that support some human and wildlife groups, and can cause adverse health effects. The failure of national regulations to consider or protect remote environments provided much of the original impetus for the Stockholm Convention. And while local or national risk assessment paradigms have afforded some guidance for the cleanup of contaminated sites, or established a basis for the regulation of certain problematic chemicals, they were ill-equipped to consider the characteristics of POPs that emerged as major health and environmental concerns in remote regions.

The “precautionary principle” has been incorporated into policy and legislative agendas of the European Union [69], and into some international treaties, such as the 1992 Rio Declaration on Environment and Development, and the Stockholm Convention on POPs. While it is viewed by some as a constraint to free-market innovation and as lacking a scientific basis [70], it has gained favor among those that point out the failure of the quantitative risk assessment paradigm to predict and/or protect the global environment [71]. The precautionary principle is based on three central elements, including the potential for harm, scientific uncertainty, and precautionary action [72]. Given the overwhelming complexities of interconnected biota and ecosystems, quantitative predictions on fate and effects for all new chemicals are a scientific impossibility. A lack of scientific certainty can be used to do one of two things: to either proceed with chemical use until unequivocal evidence emerges as a result of an adverse effect in the environment, typically decades later, or to invoke the precautionary principle by citing the uncertainty and the potential risks associated with an unknown. Invoking the precautionary principle may be perceived to constrain innovation by forcing industry to find new (and potentially costly) processes. However, its purpose is not only to prevent environmental degradation and to protect human health but also to prevent negative economic impacts “downwind” of the activity. Depending on the nature of the release, cleanup costs associated with POPs that have entered the environment can be exorbitant. For example, the Environmental Protection Agency (EPA) allocated over \$500 million in 2002 for the PCB cleanup of the Hudson River [73]. Exposure to PCBs and other toxins in the United States has been estimated to cost hundreds of billions per year [74]. Fishery closures in British Columbia due to the release of large quantities of dioxins and furans into coastal waters by pulp and paper mills prior to the onset of regulations reduced fisheries opportunities for many communities [75]. Health care costs are increasing for subsistence-oriented Inuit people suffering from elevated incidence of infections and related health problems due to POP exposure through their diet of fish and marine mammals [76]. While the precautionary principle has made a tentative foray into the risk assessment arena, numerous POPs continue to be used on a global scale. The extent to which current risk assessment methods are advanced enough to

protect the biosphere is very much unclear, something that perhaps requires a new way of thinking [77].

POPs are found in remote reaches of the world. Many are endocrine disrupting and can impact growth, brain development, reproduction, and immune function. A weight of evidence indicates that the amplification of POPs within aquatic food webs has adversely affected marine mammals, seabirds, and subsistence-oriented humans in both industrialized regions and in remote regions. Only by being more inclusive and more global in our consideration of POP risks during the lifetime of the chemical, will we truly be in apposition to prevent wanton effects.

Pesticide Risk

Risk assessment of pesticides is intriguing for a number of reasons. Pesticides are substances that are made to deliberately kill or deter species that humans have designated as pests. And, these organism-killing substances are intentionally disseminated into the environment. Because of these rather unusual aspects, pesticide risk assessment is relatively straightforward, yet, at the same time, complex.

As with risk assessment for many technologies, pesticide risk assessment primarily has been, and will continue to be, driven by government regulatory frameworks. For pesticides, risk assessment throughout most of the world largely follows the “Red Book Paradigm” [1]. This paradigm represents a formalized basis for the objective evaluation of risk in which assumptions and uncertainties are clearly considered and presented. Risk assessment typically utilizes a tiered modeling approach extending from deterministic models (Tier 1) based on conservative assumptions to probabilistic models (Tier 4) using refined assumptions [2]. In risk assessment, conservative assumptions in lower-tier assessments represent overestimates of effect and exposure; therefore, the resulting quantitative risk values typically are conservative and err on the side of safety.

Like other types of environmental health risk assessment (*see* **Environmental Health Risk Assessment**), pesticide risk assessment typically relies on the first principle that risk is a function of effect and exposure. Effects assessment includes identifying the hazard (i.e., toxin) and understanding the dose–response relationships (*see* **Dose–Response Analysis**). Because of extensive global regulatory requirements, there is usually a large and varied amount of toxicity data for pesticidal active ingredients. For example, mammalian studies (to determine potential human health effects) include acute oral toxicity (rat), acute dermal toxicity, acute inhalation toxicity (rat), primary eye irritation (rabbit), primary dermal irritation, dermal sensitization, acute delayed neurotoxicity (hen), 90-day feeding (rodent), 90-day feeding (nonrodent), 21-day dermal toxicity, 90-day subchronic dermal toxicity, 90-day inhalation (rat), 90-day neurotoxicity (hen), 90-day neurotoxicity (rat), chronic feeding (rodent), chronic feeding (nonrodent), oncogenicity (rat), oncogenicity (mouse), teratogenicity (rat),

teratogenicity (rabbit), two-generation reproduction (rat), chronic feeding/oncogenicity (rat), gene mutation, structural chromosome aberration, and other genotoxic effects. Similarly, for ecological receptors, toxicity studies include those mentioned above for mammals, acute avian oral, acute avian dietary, avian reproductive, fish, freshwater invertebrate, estuarine invertebrate (six species), fish early life stage, honey bee, and plant. From these toxicity studies, acute, subchronic, and chronic no-effect and effect levels are established, which are then compared to exposure estimates and used to characterize risk (*see* **Cancer Risk Evaluation from Animal Studies**).

Data for estimating exposures are also extensive and include measured physicochemical parameters as well as environmental fate results. Examples include octanol–water partition, hydrolysis, photodegradation in water, soil, and air, aerobic and anaerobic soil and aquatic metabolism, leaching, volatility, foliar and soil residue dissipation, groundwater fate, spray drift, and accumulation in crops, livestock, fish, and processed food (*see* **Air Pollution Risk; Environmental Risk Assessment of Water Pollution**).

Exposure assessment for pesticides is unlike many other environmental risk assessments in that normally it is not based on exposure at a specific location, but rather it relies on generic (lower-tier) exposure assumptions representing many locations. This is especially true for exposure assessments conducted by regulatory agencies during registration and reregistration activities. The rationale for this is to account for nearly all of the scenarios in which the pesticide can be applied, especially in potentially sensitive environments. There are several environmental fate models that are used to predict exposures, such as PRZM–EXAMS, GENEEC, and AgDRIFT.

Finally, risks are characterized by integrating both effect and exposure data. This is typically done by determining a ratio (often termed the *risk quotient*) between the estimated environmental concentration (EEC) and the appropriate toxic endpoint. The ratio is then compared to preexisting regulatory or other levels of concern. For example, if the EEC of a pesticide is 3 ppm in surface water and the chronic no-observed-effect-concentration for the waterflea, *Daphnia magna*, is 5 ppm, the risk quotient is 0.6. The current US Environmental Protection Agency level of concern for chronic exposure to the waterflea

is 1.0, so the value of 0.6 is below the level of concern.

In addition to generic risk assessments designed for regulatory decision-making at the time of registration, many site-specific risk assessments for pesticides have been conducted. These assessments, which can be initiated based on regulatory action, usually involve actual measurements of environmental concentrations and may also involve species-specific toxicity data. Recent advances have involved probabilistic modeling of both toxicity and exposure data using techniques such as Monte Carlo simulations. These simulations allow for a random sampling technique in which each input variable in the risk model is sampled repeatedly from a range of possible values based on the probability distribution of each variable. Then, the variability for each input is propagated into the output of the model, so that the model output reflects the probability of values that could occur. This is advantageous because it allows the decision maker to evaluate probabilities of risk occurrences and sensitivities of input values to the overall output.

Regulatory policies around the world continue to evolve in response to changes in pesticide and risk assessment technologies. For example, in the United States, risk assessments for plant-incorporated pesticides (e.g., Bt cotton) derived through genetic engineering are based on many conventional pesticide requirements, but also include many other effect and exposure data specific to gene and pesticide protein expression in a plant. Data include identification of gene source, molecular characterization of insert, copy number, gene integrity, function, specificity, mode of action, protein expression levels, protein

digestibility, homology to known allergens, acute oral toxicity, ecotoxicity, crop morphology and yield, and food and feed composition analysis.

Another major change in pesticide risk assessment in the past 10 years has been the emergence of aggregate and cumulative risk concepts. This is most evident in the passage of the US Food Quality Protection Act (FQPA) in 1996. Aggregate risk is the total risk to receptors (such as humans) from all pathways and routes of exposure to a single pesticidal active ingredient. Cumulative risk is the total risk to receptors from all sources of all pesticides that have a common mechanism of toxicity. These concepts and FQPA, in general, are intended to ensure a comprehensive, integrated approach to risk assessment and management using a consistent, health-based standard.

Environmental Risks

What are Hazardous Materials?

ROBERT K.D. PETERSON

Pharmaceuticals in the Environment

Following their use in human and veterinary medicine, significant quantities of drugs end up in the environment. Many pharmaceuticals are not readily degraded in the environment and can affect biological processes in the soil, surface water, and groundwater, and thereby be passed back into the food chain for humans and animals. Even though intensive scientific research has been conducted in this area for the last 10 years, much is still unknown.

Entry into the Environment

Since 30–95% of drugs used to treat humans and animals are later excreted, drug residues end up in the environment [1]. There they pollute surface water, soil, groundwater, and air (*see Water Pollution Risk; Soil Contamination Risk; Air Pollution Risk*) [2–5].

Drugs excreted following human use end up with municipal wastewater in sewage treatment plants and then in surface water (Figure 1). Another source of surface water contamination results from aquaculture in which pharmaceuticals are added to the water along with fish food. Following the field application of untreated manure and slurry, pharmaceuticals excreted by livestock end up in the soil and water (Figure 1). Particularly, slurry applied in agricultural areas is a source of groundwater pollution. *Via* dust particles from animal housing (manure dust, feed dust) drugs can also be passed into the air. In addition to slurry and manure, sewage sludge is also used as fertilizer, and pharmaceuticals from sewage treatment could seep into the soil and groundwater. Likewise, *via* bank filtration of surface water, drugs in municipal wastewater can get into groundwater. Drugs that land in the soil can be taken up by plants, get into the groundwater, or drain into a nearby stream. The movement of pharmaceuticals into the groundwater depends on multiple factors, such as soil type, soil moisture, soil pore distribution, and how the soil is used [6]. The risk of pharmaceutical penetration into groundwater increases with increasing solubility of the substance, reduced adsorption, and decreased degradation rate.

Degradation in the Environment

The elimination of pharmaceuticals in the environment occurs mainly by microbial degradation but it also occurs by hydrolysis, photolysis (UV light), and adsorption. Whether the degradation occurs rapidly or slowly depends on several factors, especially the chemical structure of the substance and the properties of the medium (matrix) in which the pharmaceuticals occur. Most pharmaceuticals are lipophilic and difficult to degrade, which leads to potential bioaccumulation and persistence in the environment.

In sewage treatment plants, the elimination rate of pharmaceuticals is between 7 and 99%, the average being 60%. Pharmaceuticals end up in streams that receive treated water. Biodegradation occurs more slowly in the streams than in sewage treatment plants owing to a lower stream concentration of microorganisms. This leads to increased danger of wider contamination. To some degree, these drugs are adsorbed in the sewage sludge, which is used mainly as fertilizer. The biodegradation half-life of various antibiotics lies between 10 and 104 days in surface water [7, 8].

Most medical drugs are slow to degrade in soil, so that repeated spread of slurry, manure, or sludge can result in an accumulation of pharmaceutical residues [9, 10]. Over an 80-day period sarafloxacin (fluoroquinolone) is hardly mineralized. Virginiamycin has a half-life of 87–173 days in soil. Pharmaceuticals can be taken up by plants [11].

Occurrence in the Environment

Pharmaceuticals that may be detected in wastewater and surface water include lipid regulators, analgesics, anti-inflammatory agents, β blockers, sympathomimetics, antiepileptic drugs, bronchodilators, cytostatic chemotherapy agents, and ethinylestradiol [2]. In water, following sewage treatment, drugs such as antibiotics can be detected at the microgram per liter level [2, 12]. Antibiotic concentrations up to $6\text{ }\mu\text{g l}^{-1}$ have been reported [13].

In samples of soil in agricultural areas regularly fertilized with liquid manure, tetracycline and chlortetracycline residues up to $198.7\text{ }\mu\text{g kg}^{-1}$ and $7.3\text{ }\mu\text{g kg}^{-1}$, respectively, can be detected. Since only 4.0 mg kg^{-1} tetracycline and 0.1 mg kg^{-1} chlortetracycline could be detected in the liquid manure,

Figure 1 Passage of pharmaceuticals into the terrestrial and aquatic environment following their use in human and veterinary medicine

the higher concentration in the soil is regarded as an indication of cumulative effects [14]. Fluoroquinolones, often prescribed in human medicine, have been detected in soil samples of fields on which sewage sludge had been applied [15].

At present, knowledge of pharmaceuticals in groundwater and drinking water is quite limited, but there are indications of the infiltration of drugs into these resources [16, 17]. A few drug residues have been detected at the nanogram per liter level in drinking water [18]. Studies conducted near large swine and poultry facilities in the United States also detected antimicrobials (tetracyclines, sulfonamides, β -lactams, macrolides, and fluoroquinolones) in surface water and groundwater [19], with concentrations in some cases being over $100 \mu\text{g l}^{-1}$.

Risk for the Environment

Pharmaceuticals that land in the environment can be detrimental to microorganisms, plants, insects, fish, and other life forms (Figure 2). Of special interest are detrimental effects in the areas of toxicity, genotoxicity, and development of resistance [20–23]. The so-called aquatic and terrestrial

environment is particularly at risk. Concern should be directed to possible past environmental pollution from human drugs such as antibiotics, psychopharmaceuticals, chemotherapy cytostatic drugs, and pharmaceuticals with hormonal effects. In animal production, antibiotics and antiparasitic drugs, including coccidiostats, are of particular relevance to the environment.

Antibiotics, which land in the environment, may impact microbial biodegradation in the soil and surface water, including water treatment processes in sewage treatment plants. Likewise, decomposition of dung and production of biogas may be influenced. Antiparasitic drugs can heavily damage the biocenosis in manure, slurry, water, and soil, which may, for example, lead to delayed biodegradation. Following the spread of liquid manure on soil, antibiotics may be taken up by the roots of plants, and thereby arrive in the food chain.

A particular problem is the development of bacterial resistance in the environment. Resistance genes can be carried over to other bacteria. The route of the carryover of antibiotics or resistant bacteria from animal to humans *via* meat products has been well examined; other paths *via* water, soil, and plants are less well examined [24].

Figure 2 Environmental pollution by pharmaceuticals and routes of threat to humans and animals

Minimizing the Risk

In the United States, 60–80% of the antibiotics used in animal husbandry are used as growth promoters. To avoid the development of resistant and cross-reacting strains, as well as gene toxic and carcinogenic effects, a number of pharmacologically active feed additives have been withdrawn in the European Union since 1997. As of January 1, 2006, the use of antibiotic performance enhancers is no longer allowed throughout Europe according to Commission Regulation (EC) No 183/2003 Article 11 Paragraph 2. As a result, the use of antibiotics has decreased in food animals, but not in companion animals [25], which are often treated with antibiotics used in human medicine.

Since 1993/1995, environmental risk assessment must be established before a drug developed for human medicine or for veterinary medicine is allowed to be authorized [26, 27]. In an attempt to assess environmental risk during phase I of drug trials, the predicted environmental concentration (PEC) must be determined. If specified concentrations are exceeded ($100 \mu\text{g kg}^{-1}$ in the soil or $1 \mu\text{g l}^{-1}$ in water) then risk assessment phase II takes place. In this phase, the PEC is compared to the predicted no effects concentration (PNEC). If the ratio PEC to PNEC is greater than 1, additional evaluations must be conducted.

Conclusions

Effects of pharmaceuticals in the environment have been described; particularly those antibiotics, which have an inhibitory effect on environmental bacteria, can lead to development of resistance in bacteria. At present the damage to terrestrial and aquatic life is not yet critical. Concentrations of drug residues in water consumed by humans and animals are far below therapeutic doses. Possible long term effects resulting from permanent consumption are possible, however [28].

Players in a Decision

Decisions inevitably involve people; and they may have distinct roles. The simplest decisions involve just one person, the decision maker. He or she alone provides the necessary contextual knowledge, expresses all the judgments, performs the analyses, and makes the decision. In practice, this seldom happens. Rather a group of decision makers, e.g. a management board or government department, aware that they have a decision to make, ask an analyst or, maybe, a consulting company to work with accountants, scientists, engineers, and other subject experts to gain relevant information to formulate the problem, gather and analyze data, and advise on the decision. In doing so, they consult a range of stakeholders. Thus, many will contribute to the process that leads to a decision; indeed, many may be party to the decision making (*see Group Decision*).

Roles Played in a Decision Analysis

Decision makers “own the problem”, although that does not necessarily mean that they know exactly what the problem is. In many contexts, problems related to decision arise when the decision maker becomes aware of a raft of issues that need resolving, but may be unable even to describe what a resolution might look like. For instance, a planning authority may be aware that flood risk is increasing because of climate change, yet be unclear on what the options are, whether there are other potentially relevant trends, what their objectives are, etc. However, they do know that it is their task to explore and resolve the issues. By “owning a problem”, we mean that the decision makers have the responsibility for resolving it, they have the authority to assign the necessary resources to do so, and also have the accountability for the effects of its resolution. If they lack any one of these, their abilities and motivation to deal with the issues will then be severely limited.

Decision analysis assumes at the fundamental level of the underlying modelling that all uncertainty and value judgements are provided by the decision makers: indeed, in precise terms by one decision maker [1] (*see Subjective Expected Utility; Decision Analysis*). When groups of decision makers are

involved, the situation becomes more complex. There is a need to combine their views and conclusions, and reach a consensus. Moreover, in many decision-making groups, the relative power and importance of the members of the group can differ and be further moderated by external political pressures, making some members more like experts or stakeholders than decision makers.

Experts provide economic, marketing, scientific, and other professional advice that is used to assess the likelihood of the many eventualities. Experts also provide contextual knowledge. The information that experts impart is used in the modeling and forecasting of outcomes. In principle, their advice should inform the decision makers’ subjective probabilities; however, this is not an easy process in practice. Experts can differ in their advice, so a balance has to be made. Some experts are good at encoding their knowledge into the uncertainty judgments – subjective probabilities (*see Subjective Probability*) – needed in an analysis; others are less so. There is a large literature on expert judgment, which deals with these issues and offers practical approaches for incorporating their input into a decision or risk analysis [1–4] (*see Expert Judgment*).

Stakeholders share or, at the very least, perceive that they share in the impacts arising from a decision. They have a claim, therefore, that their perceptions and values should be taken into account. The decision makers are stakeholders, if only by virtue of their accountabilities; but stakeholders are not necessarily decision makers. Within a decision analysis, their views may be taken into account within the multiattribute utility modeling [5]. It is becoming common in some areas of decision making with impacts on a wide range of stakeholders to involve them at many points in the analytic process, even if the ultimate decision is reserved for a small group of decision makers [6–8] (*see Decision Conferencing/Facilitated Workshops; Public Participation*).

Whereas experts provide contextual knowledge, *decision (or risk) analysts* have expertise in the process of decision (or risk) analysis. Their role is to manage and conduct the analysis, and is increasing these days to smooth the communication and build a shared understanding between the decision makers, stakeholders, and experts [9]. In the latter role, they are often called *facilitators*.

Discussion

Of course, it should be realized that, in practice, the distinction between roles drawn above is seldom clear. Decision makers are stakeholders and may – indeed, usually will – have relevant expertise. Similar experts can be stakeholders and *vice versa*. Ideally, however, at least one decision analyst should be dissociated from the issues, being neither an expert nor stakeholder, and certainly not a decision maker. Such independence is necessary if he or she is to manage a decision analysis in an even-handed manner.

We have concentrated on differing roles in a decision analysis; but naturally similar roles exist within a risk analysis. *Risk owners* are people who are responsible and accountable for dealing with a risk and have the authority to do so, thus their roles correspond with that of decision makers. Experts, stakeholders, and risk analysts have the obvious correspondences with the roles described above. One additional role is that of *risk manager*, who is responsible for the process of monitoring and managing the risk, and thus the protection of risk owners. Essentially, he or she is responsible for the implementation of the risk-management policy. We have not discussed implementation within decision analysis in which there are similar roles, usually, relating to tasks assigned to “middle” or operational management. However, such roles occur after the analysis has concluded.

Point Source Modeling

The term *point-source modeling* arises in a number of different contexts. In this article, we consider the specific problem of investigating spatial variation in disease risk around one or more preidentified point sources of pollution (*see Spatial Risk Assessment*). A well-known UK example is the investigation of an apparent excess of childhood leukemia cases in the vicinity of the Sellafield nuclear reprocessing plant [1–3]. The qualifying phrase “preidentified” distinguishes our topic from statistical methods used in conducting an unrestricted search for possible disease clusters throughout a prespecified geographical region [4–7], and from methods intended to characterize the general tendency for cases of a disease to exhibit spatial clustering [8, 9] or spatial variation in risk [10, 11].

We first describe an idealized point process model for the spatial distribution of individual cases of disease, then show how this model leads to case–control methods of analysis that are robust to certain kinds of departure from the idealized model. This model-based approach encourages a focus on estimating interpretable parameters using principled statistical methods, and avoids the need for *ad hoc* tests for the existence of a point-source effect.

The Idealized Model

Suppose that the population at risk can be represented as a Poisson process [12] with spatially varying intensity $\lambda(x)$. Suppose also that the risk of disease varies spatially, and that cases occur independently. Then, the cases constitute a second Poisson process with intensity $\lambda_1(x) = c_1 \lambda(x) \rho(x)$, where c_1 is the absolute risk of the disease in question and $\rho(x)$ is the spatially varying relative risk, which is the quantity of scientific interest [13]. Now suppose that controls are selected at random from the population at risk. Then, the controls constitute a third Poisson process with intensity $\lambda_0(x) = c_0 \lambda(x)$, where c_0 is the sampling fraction for the controls. It follows from standard properties of the Poisson process that, given the locations x_i of n cases and m controls, the case–control labels constitute a set of independent Bernoulli trials with the probability that an event at

x is a case given by

$$p(x) = \frac{\lambda_1(x)}{\{\lambda_0(x) + \lambda_1(x)\}} = \frac{\alpha \rho(x)}{\{1 + \alpha \rho(x)\}} \quad (1)$$

where $\alpha = c_1/c_0$ is determined by the sampling fraction for the controls. Typically, neither α nor $\lambda(x)$ is of scientific interest. Equation (1) shows how the conditioning on the case and control locations eliminates the potentially awkward function $\lambda(x)$. Furthermore, the validity of equation (1) requires no assumptions about the population at risk; its only requirements are that the controls are sampled randomly, and that cases occur independently. Hence, the model is not valid for infectious diseases, but is a reasonable starting point for investigating spatial variation in environmentally determined, noninfectious diseases.

When the controls are defined specifically to exclude cases, the argument leading to equation (1) needs to be modified accordingly but the conclusion that the parameters of $\rho(\cdot)$ can be estimated using a binary regression model for the case–control labels, still holds.

Inference

We now consider data in the form of n case locations $x_i : i = 1, \dots, n$ and m control locations $x_i : i = n + 1, \dots, n + m$. Under the stated assumptions, the log-likelihood associated with equation (1) is

$$L(\alpha, \rho) = n \log(\alpha) + \sum_{i=1}^n \log \rho(x_i) - \sum_{i=1}^{n+m} \log \{1 + \alpha \rho(x_i)\} \quad (2)$$

Parametric Models

Given a parametric specification for $\rho(x)$, inference can be carried out using standard likelihood-based methods [14]. For a single point source at location x_0 , a typical parametric model would specify $\rho(x)$ to be a nonincreasing function of the distance, $u(x)$ say, between x and x_0 , with $\rho(u) \rightarrow 1$ as $u \rightarrow \infty$. Possible choices include the following:

Near and far [15]

$$\rho(u) = \begin{cases} 1 + \gamma & : u < \delta \\ 1 & : u \geq \delta \end{cases} \quad (3)$$

Gaussian plume [16, 17]

$$\rho(u) = 1 + \gamma \exp\{-(u/\phi)^2\} \quad (4)$$

Diggle *et al.* [18] embed both equations (3) and (4) into a single, three-parameter model that combines a constant elevated risk within distance δ of the source, with a smoothly decaying risk at larger distances.

Whatever functional form is chosen for $\rho(\cdot)$, three possible extensions to the basic model are the following:

1. Adjustments for measured risk factors

If the data include the values $z_{ik} : k = 1, \dots, r; i = 1, \dots, n + m$ of each of r known or hypothesized risk factors, these can be accommodated by replacing the single parameter α in equations (1) and (2) by a linear regression term, $\alpha_i = \sum_{k=1}^r z_{ik} \beta_k$ [17]. Note that the β_k are to be interpreted as relative risk parameters.

2. Multiple sources

If there are multiple point sources at locations $x_{0k} : k = 1, \dots, r$, we write u_{ik} for the distance between x_i and x_{0k} . Then, the single term $\rho(x_i)$ in equations (1) and (2) can be replaced by a product of r terms, $\rho(u_{i1})\rho(u_{i2})\dots\rho(u_{ir})$, or by any other combination of the $\rho(u_{ik})$, if this were thought more reasonable in a particular application; see, for example, Diggle and Rowlingson [17] or Dunn *et al.* [19].

3. Directional effects

Lawson [20] and Dunn *et al.* [19] allow point-source effects to depend on orientation as well as on distance. For example, a directional version of the Gaussian plume model used in Dunn *et al.* [19] specifies

$$\rho(u, t) = 1 + \gamma \exp\{-(u \exp(-\kappa \cos(t - \theta))/\phi)^2\} \quad (5)$$

where u and t denote the distance and orientation of x relative to x_0 . The additional parameters κ and θ represent the strength and orientation of the directional effect, respectively. Their combined effect is to generate a comet-shaped plume that distinguishes

between upstream and downstream effects along the axis of orientation.

Nonparametric Models

A nonparametric model specifies $\rho(x)$ in equations (1) and (2) as an arbitrary function of $u(x)$. The model then becomes a generalized additive logistic model [21]. Statistical methods for fitting models of this kind are described in Hastie and Tibshirani [21] and in Wood [22]. Standard likelihood-based methods fail in the nonparametric setting, but penalized versions that constrain $\rho(\cdot)$ to be a smoothly varying function have been shown to give satisfactory results.

Polychlorinated Biphenyls

Polychlorinated Biphenyls: Synthesis, Applications, and Environmental Contamination

Polychlorinated biphenyls (PCBs) were widely used industrial chemicals that are readily synthesized in bulk quantities by the iron-catalyzed chlorination of biphenyl. Depending on the degree of chlorination, commercial PCBs vary from liquids to solids [1, 2]. These products have excellent industrial properties, which include chemical stability, dielectric properties, and inflammability, and were extensively used as lubricants, organic diluents, adhesives, heat transfer fluids, and dielectric fluids for capacitors and transformers. PCBs were marketed by several manufacturers worldwide and were graded according to their chlorine content (% by weight). For example, the major North American PCBs called *Aroclors* were manufactured by Monsanto Chemical Co., and Aroclors 1248 and 1260 contained 48 and 60% chlorine by weight. Another key property of commercial PCBs is that these compounds are complex mixtures of isomers and congeners (Figure 1). Since biphenyl contains five unsubstituted carbon atoms on each ring, there are a total of 209 individual PCBs (congeners) and multiple isomers within the mono and nona chlorobiphenyl group of compounds (Figure 1). High-resolution analysis of PCB mixtures has identified individual congeners in most commercial PCB formulations [3–5] and in environmental samples, which usually resemble an Aroclor 1260 pattern with 2,2', 4, 4', 5, 5'-hexachlorobiphenyl as the dominant individual PCB congener.

Environmental problems associated with PCBs were highlighted in the 1960s when these compounds were first identified in the gas chromatographic analysis for the pesticide dichlorodiphenyltrichloroethane (DDT) and its persistent metabolite dichlorodiphenyl-dichloroethylene (DDE) in various environmental media [6]. Jensen reported that PCBs were detected in environmental and human samples, and it was apparent that these compounds were present in almost every component of the global ecosystem. PCBs and DDE/DDT were among the first persistent organic pollutants (POPs) identified in the environment. The

use and manufacture of these compounds were restricted or banned in the 1970s, and there is a worldwide restriction on the production and application of all POPs. Thus, some of the major chemical properties such as lipophilicity and stability that contributed to the widespread use of PCBs ultimately lead to their downfall. Their use patterns coupled with careless disposal practices resulted in their introduction into the environment where many PCB congeners are highly persistent and bioaccumulate in fish, wildlife, and humans [7–9].

Environmental and Human Health Effects of PCBs

The effects of environmental mixtures of PCBs on fish and wildlife species has been primarily investigated by comparing and correlating levels of exposure with various adverse responses in these populations. The problem associated with these studies is that PCBs are found in the environment along with other POPs including organochlorine pesticides, DDT/DDE, polychlorinated dibenzo-*p*-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), and other chlorinated aromatic hydrocarbons. PCBs along with organochlorine compounds have been associated with reproductive problems in fish and wildlife, and there is concern regarding their role in compromising immune responses among species that inhabit polar regions where PCB levels remain high [10, 11]. Occupational exposure to relatively high levels of PCBs results in several responses including increase in 17-hydroxycorticosteroid excretion; γ -glutamyl transpeptidase activity; lymphocyte levels; skin diseases such as chloracne, folliculitis, and dermatitis; and serum cholesterol. It also leads to hepatomegaly, elevated blood pressure, and decreased serum bilirubin. These effects are highly variable among different exposed groups, and similar variability has been observed for different tumor types among various occupationally exposed cohorts [12].

There is also considerable variability in correlative hypothesis-based as well as random studies correlating exposure levels of PCBs with various outcomes. Studies in Europe and North America have extensively investigated the potential effects of *in utero* exposure to PCBs on neurodevelopment and neurobehavioral deficits in the offspring, since these effects correlate with laboratory animal

Figure 1 Structures of non-ortho substituted PCB congeners containing four or more chloro substituents and their corresponding TEF values

studies with rodent models. Jacobson and coworkers reported that, in offspring of women who consumed PCB-contaminated fish, there was a correlation between higher serum and cord blood PCB levels with decreased performance on Fagan's visual recognition memory test [13] and the Brazelton neonatal behavioral assessment scale [14]. At age 4, levels of umbilical cord serum PCBs were associated with decreased verbal and memory subtests of the McCarthy memory scales, and some deficits were also observed in children at 11 years of age [15]. Subsequent studies in the Netherlands and Germany also correlated *in utero* exposure to PCBs with neurodevelopment and behavioral deficits [16–20]. However, a recent report by the Centers for Disease Control [21] showed that relative levels of *in utero* exposure to PCBs were not correlated with a decreased intelligence quotient in offspring, even though background PCB levels were similar to those observed in the European cohorts. The inconsistencies may be related to several factors and suggest that adverse human health impacts associated with exposure to low background levels of PCBs are unresolved and require further validation.

Risk Assessment of PCB Mixtures

Risk assessment of PCB mixtures has been a formidable problem because the composition of the commercial mixtures is different from "environmental" PCB mixtures identified in different extracts.

Since the toxicity of mixtures is dependent on their individual components and concentrations as well as interactions, risk assessment of PCB mixtures requires analytical methods capable of separating and quantitating individual PCB congeners and information on the quantitative structure–toxicity relationships among PCB congeners. Mullin and coworkers first reported the high-resolution capillary gas chromatographic separation of all 209 synthetic PCB congeners [3], and subsequent improvements have made it possible to quantitate individual PCB congeners in various PCB mixtures [4, 5]. Structure–toxicity relationships have identified one class of PCB congeners that exhibit activities similar to those described for 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), namely, binding to the aryl hydrocarbon receptor (AhR) and induction of cytochrome P4501A1 (CYP1A1) and other AhR-mediated biochemical and toxic responses. Non-ortho-substituted coplanar PCBs, such as 3,3',4,4'-tetrachlorobiphenyl (TCB), 3,3',4,4',5-pentachlorobiphenyl, 3,3',4,4',5,5'-hexachlorobiphenyl, and 3,4,4',5-TCB, are substituted in both para and at least two meta positions and exhibit TCDD-like activity (Figure 2). A second group of mono-ortho-substituted analogs of the coplanar also exhibit similar activity with reduced potency [22–24]. Risk assessment of complex mixtures of PCBs, PCDDs, and PCDFs has focused on individual compounds within these mixtures that bind and activate the AhR. It has been assumed that these compounds induce additive responses that are

Figure 2 A summary of the number of PCB isomers and congeners

related to their relative potencies and concentrations. Quantitative structure–activity relationships among coplanar and mono-ortho PCBs, PCDDs, and PCDFs have provided potency or toxic equivalency factors (TEFs) of individual congeners relative to TCDD, and Figure 2 summarizes the latest World Health Organization TEFs for various PCB congeners [25]. TEF values have been selected by an expert panel from among a range of TEF values for each compound and the values can be used to calculate 2,3,7,8-tetrachlorodibenzo-*p*-dioxin equivalents (TEQs) from any mixture of PCBs (or PCDDs/PCDFs) based on the following equation:

$$\text{TEQ} = \sum [\text{PCB}]_i \times \text{TEF}_i \quad (1)$$

where $[\text{PCB}]_i$ and TEF_i represent the concentration and TEF value for individual PCB congeners in a mixture. The TEF/TEQ scheme has been developed for estimating potential exposures to or emissions of TEQs associated with mixtures of PCBs, PCDDs, and PCDFs. However, estimating health effect risks from the data is still problematic and other criticisms of this approach include nonadditive interactions with other compounds including PCBs.

Thus, risk assessment of the “TCDD-like” PCB congeners (Figure 2) has been developed and is routinely used for estimating the overall TEQs associated with PCBs in various mixtures of POPs. However, there is also evidence that other PCB congeners such as ortho-substituted analogs also contribute to the hazards and risks of PCB mixtures and methodologies for hazard and risk assessment of these compounds have not been developed.

What are Hazardous Materials?

STEPHEN SAFE AND FEI WU

Potency Estimation

A common goal in environmental risk assessment is description of a hazardous agent's toxic or otherwise-harmful effects, often for comparison with others agents of related structure or exposure. Summary measures are most useful in this regard, as these describe the potency of an agent or some product of an agent on the organism or system under study. A classic example of such a measure is the median effective dose (described below). Using such a measure, a risk assessor can make comparative statements about a series of hazardous agents as applied to a specific assay or system. When no significant response is evidenced after exposure to the agent, the potency is set equal to some boundary value that indicates no potent response. (Zero is common, although other boundary values are possible depending on the measure used to describe potency.) When a significant exposure-response relationship is present, however, some descriptive statistic that quantifies the impact of the exposure is calculated from the data.

Statistical issues dealing with estimation of potency have a long history, ranging back to bioassays of pesticides, herbicides, and other poisons [1, 2]. A number of quantitative summaries can be used to measure or define potency, each based on a slightly different feature of the observed dose-response. We consider a few of these in this article.

Median Effective Dose

A basic measure used to summarize dose-response is the *median effective stimulus* or *median effective dose*, denoted as ED_{50} . If the environmental agent is given as a concentration, we use the term *median effective concentration*, or EC_{50} . In either case, this is defined as the amount of agent required to produce a response at the median (50%) level [3]. This can be 50% of the maximum possible response in a quantal response experiment, or 50% of the control response in a decreasing-response experiment, etc. For example, suppose we measure quantal response

data as the proportion of times organisms respond (e.g., die) when exposed to a toxic stimulus. Then, since the proportions are bounded between 0 and 1, ED_{50} is the dose at which the response equals 0.50. Note here that ED_{50} is an inverse measure of potency: a higher ED_{50} suggests a weaker agent, since a greater dose is required to produce the same median result.

Obviously, ED_{50} depends upon the outcome variable under study, and the terminology has developed to indicate this. For instance, when simple lethality is the common outcome, ED_{50} is more specifically the *median lethal dose*, or LD_{50} . Note that the ED_{50} or LD_{50} is typically derived from experiments conducted over a range of dose levels for a fixed period of time. It is also possible to fix the dose level in an experiment and vary the exposure times. Then this could be used to derive a *median lethal time*, or LT_{50} , associated with the exposure. Issues of statistical estimation and testing for such quantities can be addressed using survival analytic methods [4].

An extensive literature has developed on the use of ED_{50} , EC_{50} , LD_{50} , etc.; see the early works by Irwin [5] and Fieller [6], and more contemporary discussions by Bhattacharya and Kong [7], Stukel [8], or our own work [9]. Our goal here is to distill features of the ED_{50} useful for potency estimation, particularly as they pertain to stimulus-response risk analysis.

For example, suppose we observe quantal response data where the parent distribution is binomial with sample size parameter n , and with response probability $\pi(x)$ varying over a dose x . Assume that an underlying form of the dose-response is the linear logistic form $\pi(x) = 1/(1 + \exp\{-\beta_0 - \beta_1 x\})$ or the linear probit form $\pi(x) = \Phi(\beta_0 + \beta_1 x)$, where $\Phi(z)$ is the standard normal cumulative density function. In these cases, ED_{50} is found by setting $\pi(x)$ equal to 1/2, and solving for x ; i.e., ED_{50} is the value of x that solves $1/(1 + \exp\{-\beta_0 - \beta_1 x\}) = 0.5$ or $\Phi(\beta_0 + \beta_1 x) = 0.5$, respectively. In either case, assuming $\beta_1 \neq 0$ one finds $ED_{50} = -\beta_0/\beta_1$. Next, suppose that from the observed data we calculate point estimates b_0 and b_1 for β_0 and β_1 , along with their attendant standard errors $se[b_0]$ and $se[b_1]$. Then, an estimate of ED_{50} is $\widehat{ED}_{50} = -b_0/b_1$, and large-sample $1 - \alpha$ confidence limits on the ratio $-\beta_0/\beta_1$ are based on Fieller's theorem [6, 10]. We find

$$\widehat{ED}_{50} + \frac{\gamma}{1-\gamma} \left\{ \widehat{ED}_{50} + \frac{\widehat{\sigma}_{01}}{se^2[b_1]} \right\} \pm \frac{z_{\alpha/2}}{(1-\gamma)|b_1|} \sqrt{se^2[b_0] + 2\widehat{\sigma}_{01}E\widehat{D}_{50} + se^2[b_1]E\widehat{D}_{50}^2 - \gamma \left\{ se^2[b_0] - \frac{c_{01}^2}{se^2[b_1]} \right\}} \quad (1)$$

where $\gamma = z_{\alpha/2}^2 se^2[b_1]/b_1^2$ measures departure from symmetry in the distribution of $\widehat{ED}_{50}$ (as γ approaches zero, it indicates greater symmetry), $z_{\alpha/2}$ is the upper- $\alpha/2$ critical point from a standard normal distribution, and $\widehat{\sigma}_{01}$ is the estimated covariance between the maximum likelihood (ML) estimators b_0 and b_1 . The estimated covariance is available from most logistic or probit regression computer outputs.

Example: Copper Toxicity in Fish

We illustrate estimation of median effective dose with a toxicity study in which fish were exposed to potentially toxic concentrations of copper (Cu). In this study [11], $n = 20$ fish were exposed to the metal at each of seven concentrations (in $\mu\text{g l}^{-1}$). The proportions of fish dying after 4 days were recorded: at Cu concentrations $d_1 = 0.1$, $d_2 = 0.2$, $d_3 = 0.3$, $d_4 = 0.5$, $d_5 = 1$, $d_6 = 2$, and $d_7 = 2.5$, the observed proportions were 2/20, 2/20, 5/20, 8/20, 15/20, 15/20, and 17/20, respectively. From a plot of fish mortality against the natural log of the Cu concentration, a sigmoidal response is evident. Here, we assume a logistic relationship between $\pi(x)$ and $x = \log(\text{Cu})$.

The ML estimates of the logistic regression parameters for these data can be found to be $b_0 = 0.5463$ and $b_1 = 1.3458$. The point estimate of LC_{50} is then based on $\log(\widehat{LC}_{50}) = -0.5463/1.3458 = -0.4059$, with large-sample 95% Fieller limits $-0.7199 \leq \log(LC_{50}) \leq -0.0734$. Converting to original Cu concentrations produces $\widehat{LC}_{50} = e^{-0.4059} = 0.9602 \mu\text{g l}^{-1}$, with 95% Fieller limits $e^{-0.7199} = 0.4868 \leq LC_{50} \leq e^{-0.0734} = 0.9292 \mu\text{g l}^{-1}$.

For data in the form of counts, a simple log-linear model may be employed for stimulus-response analysis: $\log\{\mu(x)\} = \beta_0 + \beta_1 x$. If the dose-response to the environmental agent is expected to produce a decrease in the mean rate of response, then we define the ED_{50} as that dose producing a 50% drop from the mean response at zero stimulus, $x = 0$. That is, under $\mu(x) = \exp\{\beta_0 + \beta_1 x\}$, a 50% reduction in

$\mu(0)$ is $\frac{1}{2} \exp\{\beta_0\}$, so we solve for x in $2 \exp\{\beta_0 + \beta_1 x\} = \exp\{\beta_0\}$. This yields $ED_{50} = -\log(2)/\beta_1$. Given stimulus-response count data under a Poisson parent distribution, we calculate the ML estimate, b_1 , of β_1 and then find $\widehat{ED}_{50} = -\log(2)/b_1$. If we also calculate the typical ("Wald") $1 - \alpha$ confidence limits $b_1 \pm z_{\alpha/2} se[b_1]$, a set of $1 - \alpha$ limits on $ED_{50} = -\log(2)/\beta_1$ is given by

$$\frac{-\log(2)}{b_1 - z_{\alpha/2} se[b_1]} < ED_{50} < \frac{-\log(2)}{b_1 + z_{\alpha/2} se[b_1]} \quad (2)$$

An informal assumption being made here is that $b_1 \leq 0$, since we expect the stimulus to decrease the mean response. Notice then that, if $z_{\alpha/2} se[b_1]$ is so large as to force $b_1 + z_{\alpha/2} se[b_1] > 0$, the interval calculation will lead to a nonsensical result. This is appropriate, however, since in this case an approximate $1 - \alpha$ confidence interval for β_1 contains zero. That is, there is no significant evidence for a dose effect, and hence no reason to calculate a potency estimate.

Bailer and Oris [12] consider the more general problem of estimating ED_{50} 's under any form of generalized linear model, of which the logistic, probit, and log-linear models are special cases. They develop core polynomial (in dose) predictor functions, and give examples with data in the form of binary survival rates, counts, and continuous measurements.

Other Levels of Effective Stimulus

Traditionally, ED_{50} has been used as a summary measure of the dose effect owing to its central location on the stimulus-response curve. However, many other response levels, such as ED_{01} , ED_{10} , ED_{90} , etc., are possible. Depending on the application, any of these may be appropriate for summary use. In general, the *effective dose* ρ is the dose that yields a $100\rho\%$ effect over the stimulus-response curve, for $0 < \rho < 1$. We denote this as $ED_{100\rho}$. For example, with quantal response under the simple linear logistic model

$\pi(x) = 1/(1 + \exp\{-\beta_0 - \beta_1 x\})$, $ED_{100\rho}$ is the value of x that solves $\rho = [1 + \exp\{-\beta_0 - \beta_1 x\}]^{-1}$. Hence,

$$ED_{100\rho} = \frac{1}{\beta_1} \left\{ \log \left\{ \frac{\rho}{1-\rho} \right\} - \beta_0 \right\} \quad (3)$$

At $\rho = 1/2$, this collapses to the ED_{50} seen above.

A similar construction is possible for any generalized linear model with quantal response data; e.g., under the simple linear probit model $\pi(x) = \Phi(\beta_0 + \beta_1 x)$ we find $ED_{100\rho} = \{z_{(1-\rho)} - \beta_0\}/\beta_1$. To estimate $ED_{100\rho}$, we substitute the ML estimates of the regression parameters, b_0 and b_1 , into the pertinent expression for $ED_{100\rho}$. Tamhane [13] reviews these and other estimation issues for measuring $ED_{100\rho}$.

We once again use Fieller's theorem to construct large-sample $1 - \alpha$ confidence limits on $ED_{100\rho}$. As long as $ED_{100\rho}$ is of the form $(\delta - \beta_0)/\beta_1$ where δ is some known constant, the form of the confidence limits from equation (1) remains unchanged. For example, under the simple linear logistic model, $ED_{100\rho}$ is of the form $(\delta - \beta_0)/\beta_1$, with $\delta = \log\{\rho/(1 - \rho)\}$. Hence, an associated set of $1 - \alpha$ confidence limits on $ED_{100\rho}$ is

$$\begin{aligned} \widehat{ED}_{100\rho} + \frac{\gamma}{1-\gamma} \left\{ \widehat{ED}_{100\rho} + \frac{\widehat{\sigma}_{01}}{se^2[b_1]} \right\} \\ \pm \frac{z_{\alpha/2}}{(1-\gamma)|b_1|} \sqrt{se^2[b_0] + 2\widehat{\sigma}_{01}E\widehat{D}_{100\rho} + se^2[b_1]E\widehat{D}_{100\rho}^2 - \gamma \left\{ se^2[b_0] - \frac{c_{01}^2}{se^2[b_1]} \right\}} \end{aligned} \quad (4)$$

where $\gamma = z_{\alpha/2}^2 se^2[b_1]/b_1^2$.

Other Potency Measures

Many other measures have been proposed to describe the potency of an environmental stimulus, taken within the context of risk estimation. Perhaps the simplest ones are known as *observed-effect levels*. Specifically, the *no-observed-adverse-effect level* (NOAEL, sometimes written simply as NOEL), is the largest level of the stimulus or dose where no adverse effect is observed in the experimental units. If the stimulus is recorded as a concentration, we often denote this as NOAEC. If at even the lowest level of the environmental stimulus a significant increase is observed over background, one calculates the *lowest-observed-adverse-effect level* (LOAEL or LOAEC).

LOAEL is the lowest level of the stimulus or dose above background where a significant adverse effect is observed. The LOAEL is also called the *least effective dose* (LED) or *minimal effective dose* (MED) by some authors; the latter is especially common in the pharmacological and medical literature.

For both NOAEL and LOAEL, estimates are determined statistically by performing a series of pairwise comparisons at each nonzero level of the stimulus against the response at the control or background level(s). Clearly, correction for multiple testing is required [14].

Numerous concerns have been raised regarding the NOAEL/LOAEL approach, since it suffers from a variety of instabilities. For instance, a NOAEL or LOAEL must by definition correspond to the actual levels of the stimulus under study. Thus, the spacing of stimulus levels is critical to these summary values, and ultimately to any risk assessments based upon them. Dose selection must be performed carefully, and include a dense enough grid of stimulus levels to estimate LOAEL and/or NOAEL with sufficient accuracy. If the experiment is poorly designed or controlled, excessively high variability can result. This

typically raises the values of NOAEL and LOAEL; thus, high variability in the response will translate into assertions of low potency (large NOAELs), regardless of the true response effect. Indeed, a design that allocates too few experimental units to the stimulus levels may overestimate or even fail to identify a NOAEL or LOAEL. These difficulties have led to concerns that observed-effect levels such as NOAEL are poor summary statistics for stimulus–response data [15, 16].

One feature that both $ED_{100\rho}$ and NOAEL share is that they are increasing measures of potency; i.e., as the potency of the stimulus decreases, the potency measure rises. Some authors find this sort of “inverse potency” to be counterintuitive, calling instead for transformations such as $1/ED_{100\rho}$ or $\log\{(1/ED_{100\rho}) + 1\}$ that recover direct proportionality, or to development of new, directly proportional

measures. For instance, suppose the form of the stimulus–response function is known and that an increasing response indicates a detrimental effect. Since in this case a sharper increase indicates a more potent stimulus, a direct measure of potency is the rate of increase in the stimulus–response curve. Mathematically, this is the slope or tangent line of the curve at each level of the stimulus. Unfortunately, for most models the slope varies with dose and so some specific dose must be chosen for measuring the curve’s slope. A common solution is to use the incremental rate of change in the dose–response just past $x = 0$. That is, given a stimulus–response function $\mu(x)$, define the potency of a hazardous agent as the stimulus–response slope at $x = 0$: this is typically the first derivative at zero, $\mu'(0)$. This “slope-at-zero” measure is motivated from low-dose estimation arguments: stimulus–response behavior at low doses of an environmental agent may approximate human responses to the agent, hence incremental change in dose–response is of greatest interest near $x = 0$. Estimates of the stimulus–response parameters and of $\mu'(0)$ can be calculated using some form of nonlinear regression.

The use of a slope-at-zero measure is not without controversy, since for some stimulus–response functions slope measures may not exist or be sensible. For example, suppose $\mu(x)$ is an unknown-order polynomial such as $\beta_0 + \beta_1 x^{\beta_2}$. For $\beta_2 > 1$, the slope at zero is $\mu'(0) = 0$ and hence will always give a zero potency for any set of data. Clearly, the choice of a stimulus–response function can influence the ultimate value of any functionally derived potency estimator, and so should be made carefully.

Measures such as NOAEL, LOAEL, $\mu'(0)$, etc., all refer to the background or control response, i.e., to organisms or subjects in clean, uncontaminated conditions. When stimulatory or protective effects are observed at low concentrations of the environmental agent, however, alternate definitions of potency may be desired. For instance, suppose that the detrimental effect is exhibited as a reduction in response, such as inhibition of reproductive capacity. Then, the potency of the environmental inhibitor might be referenced against the maximal observed reproductive response, in effect defining the reproductive impact relative to the optimal output of the organisms or subjects under study. In particular, suppose the mean reproductive response at inhibitor level x is given by the log-linear model $\mu(x) = \exp\{\beta_0 + \beta_1 x + \beta_2 x^2\}$. Then,

the response inhibitor (RI) level associated with a $100(1 - \rho)\%$ drop in capacity relative to maximal response is

$$RI_{100\rho} = -\frac{\beta_1}{2\beta_2} + \sqrt{\frac{\log(1 - \rho)}{\beta_2}} \quad (5)$$

where we assume $\beta_2 < 0$ and $\beta_1 \geq 0$. Notice that this measure is a form of $ED_{100\rho}$. The control response level and the maximal response level are the most common choices for the baseline from which an inhibition concentration is estimated. Bailer and Oris [17] discuss these and several other possibilities in more detail.

Carcinogenic Potency

Historically, in potency estimation for the special case of carcinogenic agents the Armitage and Doll [18] multistage model was used to describe how the probability of tumor/cancer presence varies as a function of exposure to the agent. A mathematically simplified form of this model for the quantal response data setting is $\pi(x) = 1 - \exp(-q_0 - q_1 - q_2 x^2 - \dots - q_k x^k)$, where $q_i \geq 0, i = 0, 1, \dots, k$, and k is a fixed integer no greater than the number of dose groups minus 1 [19]. The dose associated with a specified increase in the probability of tumor onset in individuals who would have been tumor free in the absence of exposure is often of interest. This translates to operating on an *extra risk* (ER) metric: the excess risk function is

$$ER(x) = \frac{\pi(x) - \pi(0)}{1 - \pi(0)} \quad (6)$$

We solve $ER(x) = R$ for x , where R is some small benchmark value of the ER, say 10^{-6} . For the multistage model, the excess risk function simplifies to $ER(x) = 1 - \exp(-q_1 - q_2 x^2 - \dots - q_k x^k)$. For small values of x approaching zero, this approximates further to $ER(x) \approx q_1 x$. (The requirement that x be very close to zero is critical here, since the approximation worsens dramatically as x grows large.) This motivates the definition of a common potency endpoint defined for carcinogenic responses: q_1 is often called the *unit cancer risk*, since a unit increase in dose x leads to a q_1 increase in extra (cancer) risk. In practice, we calculate a $1 - \alpha$ upper confidence limit on the q_1 parameter, say, $q_1 + z_{\alpha} se[q_1]$. This limit is often denoted as q_1^* in the literature.

Alternatively, an analog to the ED_{50} for carcinogenic responses is the *median tumorigenic dose*, or TD_{50} . This corresponds to the dose at which the proportion of tumor-free animals decreases by 50% [20–22], and can be a useful alternative for a carcinogenic potency value [23].

Benchmark Doses

The dose associated with a specified level of change relative to responses in unexposed individuals has been captured under the umbrella of *benchmark doses*, or BMDs. The specified level of change is called the *benchmark response*, or BMR (see **Benchmark Dose Estimation**). Originally, Crump [24] proposed BMD as a replacement for NOAEL in calculations of allowable daily intakes. This endpoint can be defined for responses on any scale of measurement. For example, with quantal responses we often employ the ER scale as seen in the carcinogenic potency setting discussed above. Continuous responses might be described in terms of the dose required to change the mean response in an exposed group by a specified amount relative to control group responses [25, 26]. BMD can also be defined in the context of epidemiological investigations [27] or ecotoxicological studies [28].

Relative Potency

When comparing two different chemicals, the ability of one chemical to induce an adverse response relative to the other may be of interest. As noted in Finney [2], if two chemicals (or a “preparation” versus a “standard”) are compared, then the relative potency can be defined as ρ in $F_0(x) = F_1(\rho x)$ where $F_i(\cdot)$ is the regression function relating dose to response for the i th chemical ($i = 0, 1$). Here, a dose x of chemical 0 elicits the same response as a dose ρx of chemical 1. If the $F_i(\cdot)$ functions are linear in $\log(x)$ with a common slope (as seen in *parallel line assay*) we write $F_i(x) = \alpha_0 + \beta \log(x)$. Then, the relative potency can be defined as $\rho = \exp[(\alpha_0 - \alpha_1)/\beta]$.

The concept of relative potency has been encountered in the risk assessment of mixtures, in particular, mixtures of chemicals that might be structurally related. In cases where a mixture exhibits *dose addition*, the risk of a mixture is determined by summing

the doses of the constituents of a mixture multiplied by the relative potency of each constituent [29]. *Dose addition* is linked to assumptions of a common mode of action for the mixture components, or of similarly shaped dose–response relationships for the different components [30]. The use of relative potencies to weight mixture components is also considered in the construction of toxic equivalence factors (TEFs); see, e.g. [31].

A. JOHN BAILER AND WALTER W. PIEGORSCH

Precautionary Principle

The *precautionary principle* (PP) is a term used about a set of statements all expressing the general intention that, in environmental risk policy, it is prudent to not always wait for definitive proof of harm before taking regulatory action. There are various formulations, such as the following from the third North Sea Conference in 1990 [1, p. 39]:

To take action to avoid potentially damaging impacts of substances that are persistent, toxic and liable to accumulate even when there is no scientific evidence to prove a causal link between emission and effects

and – perhaps one of the most widely known – in the Rio declaration from 1992 [2]:

Where there are threats of serious or irreversible damage, scientific uncertainty shall not be used to postpone cost-effective measures to prevent environmental degradation.

A stronger statement was formulated by a group of experts in the so-called Wingspread declaration (1998) [3]:

When an activity raises threats of harm to human health or the environment, precautionary measures should be taken even if some cause and effect relationships are not fully established scientifically.

The European Union considers the PP [4]

a general rule of public policy action to be used in situations of potentially serious or irreversible threats to health or to the environment, where there is a need to act to reduce potential hazards before there is strong proof of harm, taking into account the likely costs and benefits of action and inaction

and the Maastricht Treaty states (Article 130r(2))

Community Policy on the environment shall aim at a high level of protection taking into account the diversity of situations in the various regions of the Community. It shall be based on the precautionary principle and on the principles that preventative action should be taken, that environmental damage should as a priority be rectified at source, and that the polluter should pay.

As developed more generally by Grandjean [2], the role of the PP in the policy process needs to be

understood in the wider context that there is always a conflict between unavoidable scientific uncertainty and the policy makers' need to make decisions. The PP can then imply focus on assessing of alternatives, full-cost assessment, and a participatory decision process. It may be coupled with the right-to-know aspect, empowering the citizen to take action. And employing the PP will often imply taking actions involving more research, preventive intervention, or both.

Barnett and O'Hagan [1, p. 40] formulated the consequence of the PP for the use of scientific knowledge in setting environmental standards:

In general, we have seen that weak knowledge must lead to more stringent standards, on precautionary grounds. The value of science is to allow us, where appropriate, to relax the standards.

Critique of the Precautionary Principle

The PP has been criticized for resulting in huge expenses to prevent risks that do not exist, and for generally hampering progress, because nobody can take the risks necessary were the PP applied in general. Here, it is important to realize, as alluded to above, that there is always a judgment phase involved, when transforming current scientific knowledge into policy decisions.

It has also been stated that the PP could be problematic in a democratic society by prescribing action over and above what the democratic process itself would decide. However, a similar critique would also be valid against blind technocratic application of conventional risk assessment.

For a broad discussion of the interface of the PP, science, and regulatory activity, see [2] and the proceedings [5] of a dedicated workshop.

The Precautionary Principle, Scientific Discovery, and Statistics

Much scientific activity is based on the Popper paradigm of formulating precise hypotheses, which experimental data may then falsify. Following falsification, the researcher must formulate new hypotheses generating new experimental testing. The statistical significance test as formulated by Fisher [6] is very parallel. He stated: "A test of significance contains

no criterion for “accepting” a hypothesis. According to circumstances it may or may not influence its acceptability”.

The PP points out that this paradigm for scientific discovery should not be interpreted in the risk assessment context to say that only if a claim of no hazard has been scientifically (statistically) falsified should there be regulatory action. This is because there may be two very different reasons for the available data not to contain evidence against the hypothesis of no hazard: either there may indeed be no effect or an effect of a size below biological interest, or the data may be too noisy (often because there are too few of them) to enable any positive conclusion, the latter being termed *type II error* in statistical jargon. This dilemma is well known in biostatistics; in bioequivalence testing [7] one turns the logic upside down, testing the null hypothesis that two drugs are different by more than a given threshold, and by rejecting that hypothesis, on obtaining positive evidence of equality.

Precautionary Properties of Environmental Standards under Statistical Uncertainty

Keiding and Budtz-Jørgensen [8] outlined how statistical uncertainty affects the no observed adverse effect level (NOAEL), the benchmark approach, and hockey-stick models.

NOAEL

The NOAEL is the highest dose (in a standard toxicological animal experiment) that does not show increased risk over that of dose 0. The standard hypothesis-testing framework discussed above implies that the more evidence, the higher the NOAEL, so that the NOAEL is *antiprecautionary*.

Benchmark Approach

The Benchmark approach was introduced by Crump [9] partly motivated by an aim of avoiding the unsatisfactory antiprecautionary property of NOAEL. Statistical uncertainty will indeed lead to smaller studies having lower benchmark bounds, so that in its original form designed for standard toxicological animal experiments, the Benchmark approach is indeed precautionary.

For application to epidemiological exposure-response data, interest widens to sources of variation other than just experiment size. Budtz-Jørgensen *et al.* [10, 11] showed that the larger the variance around the dose–response curve, the larger the lower bound: an antiprecautionary property, and that if there is measurement uncertainty in the exposure variable (and there often is!), then the lower bound is overestimated, again an antiprecautionary property of the Benchmark approach.

Hockey-Stick Model

A simple approach to setting standards is to postulate that the exposure–response relationship is zero up to a certain breakpoint and increases linearly thereafter. It may be shown that small experiments, and large variation around the exposure–response relationship, both lead to overestimation of the breakpoint (antiprecautionary), while uncertainty in the exposure measurements decreases the estimate of the breakpoint (precautionary).

Concluding Remarks

The key element of the PP is the justification for acting in the face of uncertain knowledge about risks from environmental exposures. Appropriate public health action should be taken in response to limited, but plausible and credible evidence of likely and substantial harm. The PP is thereby aimed at avoiding possible future harm associated with suspected, but not conclusive, environmental risks. In parallel, the burden of proof is shifted from demonstrating the presence of risk to demonstrating the absence of risk. While the PP is not a prescription for banning the use of industrial chemicals, it requires that alternative options be evaluated to minimize the costs of surprises and maximize the benefits of innovation. Although developed in regard to social and environmental policies, the idea that policy development should not await a “final” proof or overwhelming scientific documentation may be of wider relevance.

While the legal implications of the PP are being developed within the EU legal system, the PP may also inspire some change in scientific tradition. In particular, replication has been held as a key to hypothesis testing, but the PP could, in some

situations, limit the need for repetitive verification. Further, the PP does not require testing of the null hypothesis, but rather demands information whether a potentially serious hazard may be present. Thus, an upper confidence limit may be more useful than a probability calculated in regard to the null hypothesis. Accordingly, the PP may inspire new ways of planning, conducting, and reporting research.

Precautionary Principles: Definitions, Issues, and Implications for Risky Choices

The several forms of the precautionary principle generally stand for the proposition that *when there are threats of serious or irreversible damage to the environment, scientific uncertainty should not prevent prudent actions to prevent potentially large or irreversible damage*. The main difference is in how precaution should be exercised in practice. This foundational basis for precautionary principle in many conventions and treaties, as well as pronouncements by a number of entities, requires differentiating them between those that are legally binding (e.g., Title XVI, Art. 130r of the Maastricht Treaty on European Union (EU) (1992); the Delaney Clause to the US Federal Food, Drugs, and Cosmetics Act (FFDCA)) and those that are not (as in a convention that has not been ratified by a nation that has signed it). Perhaps, the best-known enunciation of the precautionary principle is the Rio (de Janeiro) Declaration on Environment and Development of 1992.

In order to protect the environment the Precautionary Approach shall be widely applied by states according to their capabilities. Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation.

Precautionary principles should also be differentiated from other principles of precaution, such as *zero risk* or *significant risk*. All reflect varying levels of public policy, often resulting in secondary legislation that errs on the side of uniformity and ease of use by adopting defaults that are conjectural. And yet, the concern is that – because of the conflicting or incomplete results of science, or its inability to provide the answers needed at the required time and with sufficient certainty as to the potential magnitude of the adverse effects – anticipatory actions and erring on the side of caution are necessary in choices that affect occupational or public hazards. In some enunciations of those principles, the magnitude or

the severity of the potential consequences leads to disregarding their probabilities and the uncertainty in the causal connection between them and the hazard. Bans (either *all-or-none* or phased over time, and prohibitions) characterize these choices. Others believe in the proposition that precautionary decisions and choices must be guided by balancing risks, costs, and benefits, as well as being characterized by a specific level of legally demonstrable causation. In those enunciations, economic rationality guides ranking and selection of options: for instance, the use of a criterion of choice (such as the minimax, or the expected value of the magnitude of the consequences) may indicate that the *do nothing* action is superior, at least until some key uncertainties are resolved or reduced.

Regardless of the different forms of precautionary principles, it is their instrumental aspects that can create practical difficulties, not the principles themselves. The reason is that precautionary principles formulate a moral justification for acting when a hazard can *potentially* cause severe or irreversible consequences and its causation is uncertain. Yet, this moral justification can result in a suboptimal choice: *consequences that are more adverse* have been known to occur after implementation of a precautionary choice than before. This situation can occur when the choice of action, incorrect perceptions, media reiterations, ideology, political gain, and dread amplify the importance of the potential hazard and thus serve to justify that choice. Adding to these perceptual and cognitive issues, incomplete, heterogeneous, uncertain, variable, and complex scientific evidence also serves to justify a possibly scientifically unsound choice, such as one based on *political will* uninformed by a scientific risk assessment. Unless a sound and replicable analysis, based on the current state of knowledge, is coupled with the moral basis for the choice, such a choice may be (after more knowledge becomes available) incorrect and possibly illegal.

The repeated lesson, still only partially included in much political discussion, is that precautionary choices thought to prevent hazards when they are implemented, are later found to cause unanticipated harm. If that unanticipated harm could or should have been predicted, the failure to have done so is inexcusable in the sense that acting on a conjectured danger, justified by a legal maxim, is unfair – because it redirects scarce resources from more valuable societal investments. Yet, not acting by postponing preventive

action, because of large uncertainties surrounding the magnitude or severity of the hazard, can increase the magnitude of those consequences. Thus the dilemma, should society wait until the uncertainties are sufficiently resolved to trigger regulatory action, or act precipitously on a conjecture? The corollary question is, what is sufficient evidence?

Resolving this dilemma is beyond our scope, but its approach to a resolution is discussed throughout other articles in this encyclopedia (see **Axiomatic Measures of Risk and Risk-Value Models; Statistics for Environmental Justice**). For this essay, there is a simple rule that is specific to uncertain hazards: the assessment and selection of the preferred choice from the set of choices is based on *scientific analyses* of these choices, given the state of knowledge about the hazard. Each choice, consequence, probability of occurring, and so on is assessed through risk-cost-benefit balancing; the idea is to *inform* and *guide* decision makers and stakeholders, not command them to commit to a specific action. The justification of the final choice in the public interest, a matter of public policy, must account for factors that, for one reason or another, cannot be directly included in the risk-cost-benefit balancing. In the EU, for example, having to account for the *economic and social development of the community as a whole* as per Art. 134r(3) of the Treaty of Maastricht can require analyses that extend beyond the confines of a choice-specific balancing. The risk-cost-benefit analyses are essential because they account for uncertainty, causation, the value of new information and the cost of gathering it, and the utility of the payoffs associated with each option open to the decision maker. In terms of how to analyze those actions, balancing criteria such as the maximization of the expected discounted values of the payoffs, can guide the selection of the optimal (relative to the criterion adopted) act by identifying it. Those analyses are transparent, replicable, and testable *via* a number of methods, including simulations. Their extent can go beyond microeconomic consideration to include macroeconomic ones. There are costs of either action or inaction to society; nonetheless, the magnitude of the stakes justifies formal analysis of risky choices. However, conducting formal analyses is also costly. These costs include having to deal with: complex mathematical and statistical issues, data needs and their availability, and several forms of uncertainty and variability. In the

end, the results from formal analysis are constructive and meant to inform the policy-makers. Those analyses are not normative.

Precautionary Principles

An early example of legal precaution is Justinian's statement, in 527 A.D., that *the maxims of the law are to live honestly, to cause no harm unto others, and to give everyone his due*. Today, the forms of the precautionary principle generally require ranking of choices based on either a full risk-cost-benefit balancing or some accounting for the costs or risks, or both, but one should also consider, depending on the jurisdiction, factors (such as harmonization and subsidiarity) that go beyond the confines of cost-benefit analysis. Legal principles are generally unenforceable as such, although modern legislation accords them a positive and guiding force; preambles and principles are statements of general legal intent and thus lack the specificity required for enforcement. On the other hand, certain enunciations of the precautionary principle are a constitutional command, as in the EU.

Some Influential Precautionary Principles

Montreal Protocol on Substances that Deplete the Ozone Layer (Preamble, Para. 6), (Amended, 1990) ... protect the ozone layer by taking precautionary measures to control equitably total global emissions of substances that deplete it, with the ultimate objective of their elimination on the basis of developments in scientific knowledge, taking into account technical and economic considerations and bearing in mind the developmental needs of developing countries.

Convention for the Protection of the Marine Environment of the North-East Atlantic (Article 2 (2) (a)), 1992 ... The precautionary principle, by virtue of which preventive measures are to be taken when there are reasonable grounds for concern that substances or energy introduced, directly or indirectly, into the marine environment may bring about hazards to human health, harm living resources and marine ecosystems, damage amenities, or interfere with other legitimate uses of the sea, even when there is no conclusive evidence of a causal relationship between the inputs and the effects.

UN Framework Convention on Climate Change (Article 3 (3)), 1992 ... The Parties should take precautionary measures to anticipate, prevent or minimise the causes of climate change and mitigate its adverse effects. Where there are threats of serious or

irreversible damage, lack of full scientific certainty should not be used as a reason for postponing such measures, taking into account that policies and measures to deal with climate change should be cost effective so as to ensure global benefits at the lowest possible cost.

UK Strategy for Sustainable Development – DoE Consultation Paper, 1993 ... Where appropriate (for example, where there is uncertainty combined with the possibility of the irreversible loss of valued resources) actions should be based on the so-called ‘precautionary principle’ if the likely balance of costs and benefits justifies it. Even then the action taken should be in proportion to the risk.

Depending on the jurisdiction enunciating its form of precaution, it can be used by agencies or authorities to develop secondary legislation (emanating from the relevant federal statute, for example) that can range from a directive in the EU, and guidelines and standards in the United States (where standards are legally enforceable, but guidelines are not). Secondary legislation generally consists of an administrative process that result in numerical environmental or health standards (justified scientifically) designed to achieve the appropriate level of protection, after scientific peer review and public comments, as envisaged in the primary legislation (such as the US Clean Air Act (CAA)). The precautionary standard can be reviewed at the administrative levels (e.g., through the *exhaustion of remedies* doctrine), but its examination can end up in the courts or even be repealed – or made more stringent depending on the scientific information – by the legislature. For example, in American federal environmental law, some statutes have a clause that requires congressional reauthorization after some specified period, e.g., 5 years. In the EU, a new treaty can contain rewritten articles, or have articles deleted from the previous treaty, as is the case of Art. 130r (renumbered in a later treaty of the EU), although it was not changed and still has legal force within the EU. Those legal processes are lengthy and complex, with the potential for inaccurate and inefficient outcomes for society, and often result in protracted litigation. For instance, consider the statement of the Comptroller General of the United States in 1979:

Major constraints plague the Environmental Protection Agency’s ability to set standards and issue regulations. The most important factor is the inconclusive scientific evidence on which it must often base decisions. Numerous court suits result.

European Union

In the EU, the proposed but not ratified constitution’s (Charter) Part I, Title 1, Article 3 (The Union’s Objectives) states as follows:

The Union shall work for the sustainable development of Europe based on balanced economic growth, a social market economy, highly competitive and aiming at full employment and social progress, and with a high level of protection, and improvement of the quality of the environment. It shall promote scientific and technological advance.

Article II-37 (environmental protection) reports as given below:

A high level of environmental protection and the improvement of the quality of the environment must be integrated into the policies of the Union and ensured in accordance with the principle of sustainable development.

Part III (the policies and functioning of the Union) Section 5, Art. III-129 (2) states as follows:

Union policy on the environment shall aim at a high level of protection taking into account the diversity of situations in the various regions of the Union. It shall be based on the precautionary principle and on the principles that preventive action should be taken, that environmental damage should as a priority be rectified at source and that the polluter should pay.

It adds the following guidelines:

3. In preparing its policy on the environment, the Union shall take account of:
 - (a) available scientific and technical data;
 - (b) environmental conditions in the various regions of the Union;
 - (c) the potential benefits and costs of action or lack of action;
 - (d) the economic and social development of the Union as a whole and the balanced development of its regions.

Under the earlier European Treaty of Union (Maastricht, 1992), Article 130r (renumbered as Article 170 in a later Treaty) states the following legislative mandate for environmental protection policy:

2. Community policy on the environment shall aim at a high level of protection ... (and) shall be based on the precautionary principle ...

3. In preparing its policy on the environment, the Community shall take account of:
 - (i) available scientific and technical data;
 - (ii) environmental conditions in various regions of the Community;
 - (iii) the potential benefits and costs of action or lack of action;
 - (iv) the economic and social development of the Community as a whole and the balanced development of its regions.

Acting *notwithstanding* uncertainty is implicit in (2) and (i), *causal reasoning* is explicit in (i), (ii), and (iii), rational decision making is explicit in (iii), and an (unspecified) measure of risk aversion is implicit in (b). This article goes beyond cost-effectiveness and even cost–benefit analysis. Article 130r (1) also states the following European community environmental protection objectives:

- (i) preserving, protecting, and improving the quality of the environment;
- (ii) protecting human health;
- (iii) prudent and rational utilization of natural resources and
- (iv) promoting measures at international level to deal with regional or worldwide environmental problems.

The Maastricht Treaty's Titles II and IV, moreover, contains language such as "sustainable growth" "quality of life" environmental protection as well as "economic and social cohesion". Yet, what should be clear is that the EU treaties do call for the *precautionary principle* but fail to define it. Nonetheless, the sections of Art. 130r do provide the constraints to be placed on precautionary justifications of policy choices (made by the European commission, for example, as discussed below).

Precautionary reasoning creates a threshold above which a public institution must act to prevent harm, provided such actions are demonstrably cost-beneficial, even when allowing for uncertainty. For any given hazard-to-risk situation that falls under any of the forms of precaution, intuitively, and factually, there is a *tolerable window* of low risk where precautionary actions are dormant, but during which further data must be developed, analyzed, and used to determine if the hazard is of societal concern. Below the lower limit of that interval, no action would take place. Above the upper limit, actions can be taken,

provided that the risk-cost-benefit balancing is positive. The EU context of the precautionary principle points to decisions justified by a formal account of the changes in risk, cost, and benefit. Essentially, it commands making rational decisions based on the efficient social choices by balancing of *the potential benefits and costs of action or lack of action*.

The EU context for the precautionary principle is legal. The European Court of Justice (ECJ)'s review of the EU commission decision to ban export of beef from the United Kingdom to reduce the risk of bovine spongiform encephalopathy (BSE) transmission (Judgments of May 5, 1998, cases C-157/96 and C-180/96) issued the following suggestion:

Where there is uncertainty as to the existence or extent of risks to human health, the institutions may take protective measures without having to wait until the reality and seriousness of those risks become fully apparent.

The Court reasoned as follows:

approach is borne out by Article 130r(1) of the EC Treaty, according to which Community policy on the environment is to pursue the objective *inter alia* of protecting human health. Article 130r(2) provides that that policy is to aim at a high level of protection and is to be based, in particular, on the principles that preventive action should be taken and that environmental protection requirements must be integrated into the definition and implementation of other Community policies.

The ECJ, however, did not provide the framework explicitly to deal with the difficulties inherent to making these decisions. In particular, it did not characterize the formal (statistical) meaning of *fully apparent risks* nor how to deal with the complexities of causation that invariably arise in the situations that trigger precautionary reasoning based on the precautionary principle.

In case T-70/99, the president of the EU court of first instance (CFI) referred to this ECJ judgment, stating that *the protection of public health should undoubtedly be given greater weight than economic considerations*. Nonetheless, because of consistency with the treaty of Union, case law, and subsequent treaties, precautionary decisions must be based on sound analytical – and thus replicable – reasoning or else the assertion that *protection requirements must be integrated into the definition and implementation of other community policies* may not be met

with accuracy and consistency. That is to say, the characteristics (factual and conjectural) of a situation will be different from another, but the formalities inherent to Art. 130r precautionary principle apply to all equally.

Consider the European Council Regulation (December 17, 1998) that resulted in the withdrawal of four antibiotics, including virginiamycin, from the list of additives in animal feeds. Some of the scientific evidence was that pathogen bacteria, which become resistant to the antibiotics due to feeding of antibiotic additives to livestock, could get transferred from animals to humans and thus make them more resistant to treatment with antibiotics. Pfizer and Alpharma, directly affected by the ban, sued in the CFI (a lower court in the EU judicial system) to annul that regulation because of the danger that it would cause *serious and irreparable damage* to them. The CFI found against these two companies because: (i) they could sell their products on markets outside the Community, (ii) two of their European plants would probably not be closed, and (iii) that the ban issued was not final.

Pfizer (virginiamycin)

Although the CFI held that “preventive measures can be adopted without having to wait until the reality and seriousness of the risks being fully apparent”, nonetheless, preventive measures cannot be based on a scientific conjecture, but can be taken where there is a *real risk*. Such risk entails some probability that the negative effects, which the measure should prevent, will occur, but such probability cannot be *zero risk*. The CFI held that an agency must develop a risk assessment, based on both science (*risk assessment*) and policy (*risk management*), to decide on the appropriate action. The role of science is held to be essential; the ultimate outcome is based on policy, informed by science. For virginiamycin, the Scientific Committee for Animal Nutrition (SCAN), an expert committee specifically established to provide scientific advice to the EU to animal feedstuffs, concluded that there was insufficient scientific evidence that virginiamycin would cause the alleged hazard, and thus did not advise the EU to withdraw it from the market.

Alpharma (Bacitracin zinc)

Here, SCAN was not asked to review the scientific evidence, before the council wrote the regulation; nonetheless, the council concluded that it was risky to

human health. Not referring to SCAN is only appropriate in *exceptional circumstance and when there are adequate guarantees*, as the CFI stated, of *scientific objectivity*. The CFI upheld the regulation, stating that EU institutions could take a *horizontal approach* to an *entire class of antibiotics by systematically excluding the use as additives in feeding stuffs of products also used in human medicine*. The CFI found those “exceptional circumstances”, and held that SCAN’s advice is not binding, unless explicitly stated to be so in the legislation, and that it was not mandatory for the commission to seek such advice.

Peel (2004) concludes the following (footnotes omitted):

Despite the limited nature of the scientific evidence available to the Community institutions and the lack of anything indicating an immediate health threat, the CFI found that the Commission and Council had not committed any manifest errors in their review of scientific studies and assessment of the risks to health prior to adopting the measure.¹²⁹ Although the Court stressed that regulatory authorities must have at their disposal scientific information which is sufficiently reliable and cogent to allow them to understand the ramifications of the scientific questions raised and to make a decision on policy measures in full knowledge of the facts, the CFI displayed a strongly deferential attitude when reviewing the institutions’ interpretation of the scientific material and their judgments as to the existence of genuine scientific uncertainty.

The CFI found that the uncertainty in the use of antibiotics as additives to animal diets and human resistance to those antibiotics justified their ban by appeal to the Art. 130r Precautionary Principle. This ban is consistent (proportionate) with protecting human health according to the *high level of protection* of this article. Unfortunately, when virginiamycin, macrolides, and other animal antibiotics used to prevent animal illnesses and enhance performance were indeed withdrawn in several European countries, in keeping with this interpretation of the precautionary principle, bacterial illness rates in both chickens and humans increased dramatically.

Precautionary principles tend to place the burden of proof about who causes the hazardous situation, leading to risk on those who market or develop a product. An example of such a shift (Commission of the European Communities, 2001) is as follows: [*r*]responsibility to generate knowledge about chemicals should be placed on industry. Industry should

also ensure that only chemicals that are safe for the intended purposes are produced. However, partly to avoid spurious litigation, the European Commission (EC's) commentary also states the following:

A scientific evaluation of the potential adverse effects should be undertaken based on the available data ... [T]his requires reliable scientific data and logical reasoning, leading to a conclusion which expresses the possibility of occurrence and the severity of a hazard's impact on the environment, or health of a given population ...

The commentary then concludes that *precautionary measures must not be applied to address conjectured risks*. As the CFI held:

It is necessary, first, to define the 'risk' which must be assessed when the precautionary principle is applied ... A preventive measure cannot properly be based on a purely hypothetical approach to the risk, founded on mere conjecture which has not been scientifically verified ...

Views from Other Jurisdictions

The Canadian government proposed guiding principles for risk analysis that include the precautionary principles (Government of Canada, 2001, *The Need for a Federal Approach*, http://www.tbs-sct.gc.ca/pubs_pol/dcgpubs/RiskManagement/rmf-cgr_e.html 3), which are given below.

- A. Follow-up scientific activities, including further research and scientific monitoring, are a key part of the application of the precautionary approach. ... (a)
- B. "Sufficiently sound information base" should be interpreted as sound and reasonable scientific information, including uncertainties that, through evaluation ... [t]hat is, while scientific information would not need to demonstrate definitively the cause-and-effect relationship between risk and serious harm, it would demonstrate that such a risk exists. (And)
- C. Generally, the responsibility for providing the scientific information base (the burden of proof) should rest with the party who is taking an action associated with potential or serious harm. ...

An important issue that often goes unstated is addressed by Canada (Gov of Canada, 2001, http://www.tbs-sct.gc.ca/pubs_pol/dcgpubs/RiskManagement/rmf-cgr_e.html 3), which points out the following:

... it is impossible to prove a negative (e.g., to prove categorically that something will cause no harm, or to prove with absolute certainty that something bad might not happen or to prove that something is not harmful), but possible to demonstrate that "reasonable testing" was done with no evidence of harm. ... Precautionary measures should be cost-effective, with the goal of generating (i) an overall net benefit for society at least cost, and (ii) efficiency in the choice of measures. ... The real and potential impacts of making a precautionary decision (whether to act or not to act), including social, economic, and other relevant factors, should be assessed. Moreover, consideration of risk-risk trade-offs or comparative assessments of different risks would generally be appropriate (although this may not be possible in circumstances where urgent action is needed). This can ensure that society receives net benefits from decision making, and that the precautionary approach is not used as an unnecessary or unintentional barrier to innovation or technological change. ... As the precautionary approach is, by definition, an evolutionary process, precautionary measures should be monitored on an ongoing basis so that new scientific data that alters cost-effectiveness considerations can be incorporated (including performance monitoring results).

In India, its Supreme Court defined the precautionary in the case *A. P. Pollution Control Board v. Nayudu*, as follows:

The principle of precaution involves the anticipation of environmental harm and taking measures to avoid it or to choose the least environmentally harmful activity. It is based on scientific uncertainty. Environmental protection should not only aim at protecting health, property, and economic interest but also protect the environment for its own sake. Precautionary duties must not only be triggered by the suspicion of concrete danger but also by concern or risk potential.

Importantly, because of the complex nature of uncertain causation, that court also shifted the burden of proof stating that "*the party ... maintaining a less-polluted state should not carry the burden of proof and the party who wants to alter it, must bear this burden.*"

Although this shift of the burden of proof is established in some "common law" countries, such as the United States in both tort and environmental law, bearing that burden requires the analysis of uncertain scientific evidence and meeting both scientific and legal causation. In particular, UK courts have rejected shifting the burden of proof in *Wilsher v. Essex Area*

Health Authority (1988), which reconfirms the tenet that the burden of proof remains on the plaintiff, although Lord Wilberforce made an unsuccessful attempt to reintroduce it in the *McGhee* case, decided in the House of Lords. It is yet unclear as to how the primacy of European law, as well as an eventual constitution for the EU, squares with the UK's rejection (of reversing the burden of proof) because it raises significant conflict of laws with the EU's laws (e.g., with regulations and directives) regarding precautionary measures.

US law contains several variants of the precautionary principle. The precautionary language of the federal legislation that direct the regulatory role of US federal agencies has many facets, unlike the EU's Art. 130r Precautionary Principle. A fundamental difference is the US specificity, at least in some instances of the statutory language:

- In the case of threshold effects an additional ten-fold margin of safety for the pesticide chemical residue shall be applied for infants and children ... (Federal Food, Drugs, and Cosmetics Act, § 408 (b)(2)(C)(b)).
- The Administrator shall, specify, to the extent practicable: 1) Each population addressed by any estimate of public health effects; 2) The expected risk or central estimate of risk for the specific populations; 3) Each appropriate upper-bound or lower-bound estimate of risk ... (Safe Drinking Water Act, § 300g-1 (b)(3)).
- The Administrator shall ... [add] pollutants which present, or may present, through inhalation or other routes of exposure, a threat of adverse human health effects ... or adverse environmental effects through ambient concentrations, bioaccumulation, deposition, or otherwise but not including releases subject to regulation under subsection (r) of this section as a result of emissions to air... (Clean Air Act, § 112(b)(2)).
- Provide an ample margin of safety to protect public health or to prevent an adverse environmental effect (Clean Air Act, § 112(f)).
- To assure chemical substances and mixtures do not present an unreasonable risk of injury to health or the environment (Toxic Substances Control Act, TSCA § 2(b)(3)).
- Function without unreasonable and adverse effects on human health and the environment (FIFRA § 3).
- Necessary to protect human health and the environment (Resources Conservation and Recovery Act, RCRA § 3005 as amended).
- Provide the basis for the development of protective exposure levels (National Contingency Plan) NCP § 300.430(d).
- Adequate to protect public health and the environment from any reasonably anticipated adverse effects (Clean Water Act CWA § 405(d)(2)(D)).

However, primary legislation can still be vague and thus open the road for litigation. Moreover, even the language of a single statute, the CAA, which directs the US environmental protection agency (EPA's) Office of Air and Radiation (OAR), shows that there are differences in the level of precaution to be adopted by this agency. The range is remarkable:

- a) Protect public health with an adequate margin of safety (Clean Air Act, CAA § 109).
- b) Provide an ample margin of safety to protect public health or to prevent an adverse environmental effect (OAR; CAA § 112(f)).
- c) Protect the public welfare from any known or anticipated adverse effects (OAR; CAA § 109).
- d) [Not] cause or contribute to an unreasonable risk to public health, welfare, or safety (OAR; CAA § 202(a)(4)).

The role of risk analysis, under Section 112(f)(2) (B) of the CAA, is that the US EPA uses a two-step risk assessment for setting residual risk standards (articulated in the US EPA's 1989 benzene National Standards for Hazardous Air Pollutants (NESHAP) (Federal Register, 54: 38044)) as given below (US EPA, 2004):

- 1) A first step, in which EPA ensures that risks are 'acceptable.' As explained in the Benzene NESHAP, in this step EPA generally limits the maximum individual risk, or 'MIR,' to no higher than approximately 1 in 10 thousand. The benzene NESHAP defines the MIR as the estimated risk that a person living near a plant would have if he or she were continuously exposed to the maximum pollutant concentrations for a lifetime (70 years).
- 2) A second step, in which EPA establishes an 'ample margin of safety.' In this step, EPA strives to protect the greatest number of persons possible to an estimated individual excess lifetime cancer risk level no higher than approximately 1 in 1 million. In judging whether risks are acceptable and whether an ample margin of safety is provided, the benzene NESHAP (under the Clean Air Act) states that EPA will consider not only the magnitude of individual risk, but 'the distribution of risks in the exposed population, incidence,

the science policy assumptions and uncertainties associated with the risk measures, and the weight of evidence that a pollutant is harmful to health.' . . . Note that the ample margin of safety analysis . . . also includes consideration of additional factors relating to the appropriate level of control, 'including costs and economic impacts of controls, technological feasibility, uncertainties, and any other relevant factors.'

Another US federal statute, comprehensive environmental response, compensation and liability act (CERCLA) (42 U.S.C. 9605 (CERCLA, 1980)) Superfund Amendments and Reauthorization (SARA) Act of 1986, requires that actions selected to clean up hazardous waste sites be protective of human health and the environment. The National Oil and Hazardous Substances Pollution Contingency Plan, NCP, implements CERCLA (US EPA, 2004). The NCP establishes the overall approach for determining appropriate remedial action at superfund sites with the national goal to select remedies that *are protective of human health and the environment, and that maintain protection over time*. One of the policy goals of the program is to protect against a high end, as distinguishable from the worst-case, individual exposure. It is based on the reasonable maximum exposure (RME), which is the highest exposure that is reasonably expected to occur at a superfund site. It is conservative, but within a realistic range of exposure (US EPA, 2004). In addition to RME individual risk, EPA evaluates risks for the *central tendency exposure* (CTE) estimate, or average exposed individual. EPA received comments implying that the RME represents a *worst-case or overly conservative exposure estimate*. Thus, the RME is not a worst-case estimate – *the latter would be based on an assumption that the person is exposed for his or her entire lifetime at the site* (US EPA, 2004).

The reasonable maximum exposure scenario is 'reasonable' because it is a product of factors, such as concentration and exposure frequency and duration, that are an appropriate mix of values that reflect averages and 95th percentile distribution . . . The RME represents an exposure scenario within the realistic range of exposure, since the goal of the Superfund program is to protect against high-end, not average, exposures. The "high end" is defined as that part of the exposure distribution that is above the 90th percentile, but below the 99.9th percentile.

Discussion

Assessing and implementing actions to limit exposure to the hazardous situation and thus reduce risk and monitoring public risky choices under a precautionary principle are the *explicit* results of *legislative* fiat that are inherently costly to society, because budgets are not infinite and resources are constrained. That is, it is possible that the improperly justified allocation under a precautionary principle would divert some scarce resources to pay for an action that is much less protective than its next best alternative, as measured by the opportunity cost of the action not taken.

Clearly, when the magnitude of the consequences is large and the probabilities are also large, quick action becomes imperative. Precautionary principles argue for both circumspection and prevention when the magnitude of the potential adverse event is large or severe, but its probability is relatively small. Arguing for costly action when the causes of the adverse event are either poorly understood or conjectural is unlikely to result in an equitable distribution of risks and benefits, if an action developed on such basis is taken. When the *expected loss* of a choice is small (e.g., a fractional average cancer), some can argue *against* taking immediate precautionary action if the magnitude of the expected value is smaller than some legal minimum (in legal terms, it is no longer *de minimis*). Others look at the magnitude and severity of the probable outcome, but keep probability and magnitude separate and do not multiply them, thus arguing for action even when the probability is small but the magnitude of the adverse consequences is large. These alternative situations reinforce the suggestions that, regardless of their wording, the enunciation of the precautionary principle should contain specific guidance on the strength of the scientific evidence and the explicit recognition of time-dependent changes in the scientific information.

Premium Calculation and Insurance Pricing

The price of insurance is the monetary value for which two parties agree to exchange risk and “certainty”. There are two commonly encountered situations in which the price of insurance is subject of consideration: when an individual agent (for example, a household), bearing an insurable risk, buys insurance from an insurer at an agreed periodic premium; and when insurance portfolios (that is, a collection of insurance contracts) are traded in the financial industry (e.g., being transferred from an insurer to another insurer or from an insurer to the financial market (securitization)).

Pricing in the former situation is usually referred to as *premium calculation* (see **Insurance Applications of Life Tables**), while pricing in the latter situation is usually referred to as *insurance pricing* (see **Insurance Pricing/Nonlife; Risk Measures and Economic Capital for (Re)insurers; Actuary; Individual Risk Models; Multistate Models for Life Insurance Mathematics; Risk Attitude**), although such a distinction is not unambiguous. In this article, we refrain from such an explicit distinction, although the reader may verify that some of the methods discussed are more applicable to the former situation and other methods are more applicable to the latter situation.

To fix our framework, we state the following definitions and remarks:

Definition 1 (Fundamentals) We fix a measurable space $(\Omega, \mathcal{F})$ where Ω is the outcome space and $\mathcal{F}$ is a $(\sigma\text{-})$ algebra defined on it. A risk is a random variable defined on $(\Omega, \mathcal{F})$; that is, $X: \Omega \rightarrow \mathbb{R}$ is a risk if $X^{-1}((-\infty, x]) \in \mathcal{F}$ for all $x \in \mathbb{R}$. A risk represents the final net loss of a position (contingency) currently held. When $X > 0$, we call it a loss, whereas when $X \leq 0$, we call it a gain. The class of all random variables on $(\Omega, \mathcal{F})$ is denoted by $\mathcal{X}$.

Definition 2 (Premium calculation principle (pricing principle)) A premium (calculation) principle or pricing principle π is a functional assigning a real number to any random variable defined on $(\Omega, \mathcal{F})$; that is, π is a mapping from $\mathcal{X}$ to $\mathbb{R}$.

Remark 1 In general, no integrability conditions need to be imposed on the elements of $\mathcal{X}$. In the absence of integrability conditions, some of the premium principles studied below will be infinite for subclasses of $\mathcal{X}$. Instead of imposing integrability conditions, we may extend the range in the definition of π to $\mathbb{R} \cup \{-\infty, +\infty\}$. In case $\pi[X] = +\infty$, we say that the risk is unacceptable or noninsurable.

Remark 2 Statements and definitions provided below hold for all $X, Y \in \mathcal{X}$ unless mentioned otherwise.

No attempt is made to survey all of the many aspects of premium calculation and insurance pricing. For example, we largely ignore contract theoretical issues, and largely neglect insurer expenses and profitability, as well as solvency margins.

In the recent literature, premium principles are often studied under the guise of risk measures; see Föllmer and Schied [1] and Denuit *et al.* [2] for recent reviews of the risk measures literature.

Classical Theories and Some Generalizations

Classical actuarial pricing of insurance risks mainly relies on the economic theories of decision under uncertainty (see **Mathematics of Risk and Reliability: A Select History; Uncertainty Analysis and Dependence Modeling**), in particular on Von Neumann and Morgenstern’s [3] expected utility theory and Savage’s [4] subjective expected utility theory; the interested reader is referred to the early monographs of Borch [5, 6], Bühlmann [7], Gerber [8], and Goovaerts *et al.* [9] for expositions and applications of this theory in insurance economics and actuarial science. Using the principle of equivalent utility (see **Axiomatic Models of Perceived Risk; Axiomatic Measures of Risk and Risk-Value Models; Risk Measures and Economic Capital for (Re)insurers**) and specifying a utility function, various well-known premium principles can be derived. An important example is the exponential premium principle, obtained by using a (negative) exponential utility function, having a constant rate of risk aversion.

The Principle of Equivalent Utility

Consider an agent who is carrying a certain risk. Henceforth, he will be referred to as the “insured”

even though he might decide not to purchase the insurance policy he is offered. Furthermore, consider an insurance company offering an insurance policy for the risk.

We consider below a simple one-period-one-contract model, in which the insurer's wealth at the beginning of the period is w and the loss incurred due to the insured risk during the period is X , so that the insurer's wealth at the end of the period is $w + \pi[X] - X$. The loss X is uncertain and is here represented by a nonnegative random variable with some distribution $\mathbb{P}[X \leq x]$. We assume that both the insurer and the insured have preferences that comply with the expected utility hypothesis.

Let us first consider the viewpoint of the insurer. For a given utility function $u : \mathbb{R} \rightarrow \mathbb{R}$, we consider the expected utility $\mathbb{E}[u(w + \pi[X] - X)]$. In the Von Neumann–Morgenstern framework (see **Mathematics of Risk and Reliability: A Select History**), the utility function u is subjective, whereas the probability measure is assumed to be objective, known, and given. In the more general framework of Savage [4] (see **Subjective Probability; Clinical Dose–Response Assessment**), the probability measure also can be subjective. In the latter framework, the probability measure need not be based on objective statistical information, but may be based on subjective judgments of the decision situation under consideration, just as u is.

From the expected utility expression, an *equivalent utility principle* (also known under the slight misnomer *zero utility principle* (see **Subjective Probability; Clinical Dose–Response Assessment**)) can be established as follows: for a given random variable X and a given real number w , the equivalent utility premium $\pi^- [X]$ of the insurer is derived by solving

$$\mathbb{E}[u(w + \pi[X] - X)] = u(w) \quad (1)$$

Under the assumption that u is continuous (which is implied by the usual set of axioms characterizing expected utility preferences) and provided that the expectation is finite, a solution exists. If the insurer is risk-averse (which for expected utility preferences is equivalent to the utility function being concave), one easily prove that $\pi^- [X] \geq \mathbb{E}[X]$. The insurer will sell the insurance if and only if he can charge a premium $\pi[X]$ that satisfies $\pi[X] \geq \pi^- [X]$.

Next, we consider the viewpoint of the insured.

will be preferred to full self insurance, which leaves the insured with final wealth $\bar{w} - X$, if and only if $\bar{u}(\bar{w} - \pi[X]) \geq \mathbb{E}[\bar{u}(\bar{w} - X)]$, where $\bar{u}$ denotes the utility function of the insured. The equivalent utility premium $\pi^+ [X]$ is derived by solving

$$\bar{u}(\bar{w} - \pi[X]) = \mathbb{E}[\bar{u}(\bar{w} - X)] \quad (2)$$

The insured will buy the insurance if and only if $\pi[X] \leq \pi^+ [X]$. One easily verifies that a risk-averse insured is willing to pay more than the pure net premium $\mathbb{E}[X]$. An insurance treaty can be signed both by the insurer and by the insured only if the premium satisfies $\pi^- [X] \leq \pi[X] \leq \pi^+ [X]$.

Example 1 Consider an agent whose preferences can be described by an exponential utility function

$$u(x) = \frac{1}{\alpha} (1 - e^{-\alpha x}), \quad \alpha > 0 \quad (3)$$

where α is the coefficient of absolute risk aversion. We find that

$$\pi^+ [X] = \frac{1}{\alpha} \log(m_X(\alpha)) \quad (4)$$

where $m_X(\alpha)$ is the moment generating function of X evaluated in α . We note that for this specific choice of the utility function, $\pi^+ [X]$ does not depend on w . Furthermore, notice that the expression for $\pi^- [X]$ is similar. However, now α corresponds to the risk aversion of the insurer. When $\alpha \downarrow 0$ (i.e., for a risk-neutral agent), the exponential premium reduces to $\mathbb{E}[X]$.

Different specifications of the utility function yield different expressions for $\pi^+ [X]$ and $\pi^- [X]$. It is not guaranteed that an explicit expression for $\pi^+ [X]$ or $\pi^- [X]$ is obtained. In a competing insurance market, the insurer may want to charge the lowest “feasible” premium, in which case π will be set equal to π^- .

Rank-Dependent Expected Utility and Choquet Expected Utility. Since the axiomatization of expected utility theory by Von Neumann and Morgenstern [3] and Savage [4] numerous objections have been raised against it; see e.g., Allais [10] (see **Bayes’ Theorem and Updating of Belief; Utility Function**). Most of these relate to the descriptive power of the theory, that is, to empirical evidence of the extent to which agents’ behavior under risk and uncertainty coincides with expected utility theory.

Motivated by empirical evidence that individuals often violate expected utility, various alternative theories have emerged, usually termed as *nonexpected utility theories*; see Sugden [11] for a review.

A prominent example is the *rank-dependent expected utility* (RDEU) theory (see **Risk Attitude**) introduced by Quiggin [12] under the guise of *anticipated utility theory*, and by Yaari [13] for the special case of linear utility. A more general theory for decision under uncertainty (rather than decision under risk), which is known as *Choquet expected utility* (CEU) theory, is due to Schmeidler [14]; see also Choquet [15], Greco [16], Schmeidler [17], and Denneberg [18].

Consider an economic agent who is to decide whether or not to hold a lottery (prospect) denoted by the random variable V . Under a similar set of axioms as used to axiomatize expected utility theory, but with a modified additivity axiom, Yaari [13] showed that the amount of money c at which the decision maker is indifferent between holding the lottery V or receiving the amount c with certainty can be represented as follows (in his original work, Yaari [13] restricts attention to random variables supported on the unit interval; also, Yaari [13] imposes a strong continuity axiom to ensure that g is continuous; we present here a more general version):

$$c = - \int_{-\infty}^0 (1 - g(\bar{F}_V(v))) dv + \int_0^{+\infty} g(\bar{F}_V(v)) dv \quad (5)$$

with $\bar{F}_V(v) := 1 - \mathbb{P}[V \leq v]$. Here, the function $g : [0, 1] \rightarrow [0, 1]$ is nondecreasing and satisfies $g(0) = 0$ and $g(1) = 1$. It is known as a *distortion function*. Provided that g is right continuous, that $\lim_{x \rightarrow +\infty} xg(\bar{F}(x)) = 0$ and that $\lim_{x \rightarrow -\infty} x(1 - g(\bar{F}(x))) = 0$, expression (5) is an expectation calculated using the distorted distribution function $F_g^*(x) := 1 - g(\bar{F}(x))$, that is, $c = \int_{-\infty}^{+\infty} x dF_g^*(x)$. In the economics literature, c is usually referred to as the *certainty equivalent*. Applying the equivalent utility principle within the RDEU framework amounts to solving

$$\int_{-\infty}^{+\infty} (w + \pi[X] - X) dF_g^*(x) = w \quad (6)$$

from which we obtain the *distortion premium principle* (see **Insurance Pricing/Nonlife; Risk Measures and Economic Capital for (Re)insurers**):

$$\pi^-[X] = \int_{-\infty}^{+\infty} x dF_g^*(x) \quad (7)$$

with $\bar{g}(p) = 1 - g(1 - p)$, $0 \leq p \leq 1$, being the *dual distortion function*. The premium principle (7) and its appealing properties were studied by Wang [19] and Wang *et al.* [20].

Example 2 (PH distortion) Consider, as an example, the proportional hazard (PH) distortion function given by $\bar{g}(x) = x^{1/\alpha}$, $\alpha \geq 1$, advocated by Wang [19] and Wang *et al.* [20]. The value of the parameter α determines the degree of risk aversion: the larger the value of α , the larger the risk aversion with $\alpha = 1$ corresponding to the nondistorted (base) case. In this case,

$$\pi^-[X] = - \int_{-\infty}^0 (1 - (\bar{F}_X(x))^{1/\alpha}) dx + \int_0^{+\infty} (\bar{F}_X(x))^{1/\alpha} dx \quad (8)$$

The decumulative distribution function (or tail distribution function) $\bar{F}_X$ provides a natural insight into how to distribute insurance premiums between different layers of insurance, since the net premium for a layer $(a, a + b]$ can be computed as

$$\int_a^{a+b} \bar{F}_X(x) dx \quad (9)$$

An important concept in the axiomatization of RDEU as well as CEU is *comonotonicity* (see **Comonotonicity**). We state the following definition:

Definition 3 (Comonotonicity) A pair of random variables $X, Y : \Omega \rightarrow (-\infty, +\infty)$ is comonotonic if

- (a) there is no pair $\omega_1, \omega_2 \in \Omega$ such that $X(\omega_1) < X(\omega_2)$ while $Y(\omega_1) > Y(\omega_2)$;
- (b) there exists a random variable $Z : \Omega \rightarrow (-\infty, +\infty)$ and nondecreasing functions f, g such that

$$\begin{aligned} X(\omega) &= f(Z(\omega)), \\ Y(\omega) &= g(Z(\omega)), \quad \text{for all } \omega \in \Omega \end{aligned} \quad (10)$$

As we will see below, the premium principle (7) is additive for sums of comonotonic risks.

Another prominent example of a nonexpected utility theory is *maximin expected utility theory* introduced by Gilboa and Schmeidler [21]. It involves the evaluation of worst case scenarios. Laeven [22] proposes a theory that unifies CEU and maximin expected utility theory for linear utility.

Equilibrium Pricing and Pareto Optimality

Bühlmann [23] argued that in contrast to classical premium principles that depend on characteristics of the risk on its own, it is more realistic to consider premium principles that take into account general market conditions (e.g., aggregate risk, aggregate wealth, dependencies between the individual risk and general market risk). Bühlmann derived an *economic premium principle* (see **Optimal Risk-Sharing and Deductibles in Insurance**) in which a functional $\pi[\cdot, \cdot]$ assigns to a random variable X representing the risk to be insured and a random variable Z representing general market risk, a real number π ; that is, $\pi : (\mathcal{X}, \mathcal{Z}) \rightarrow \mathbb{R}$. We will briefly review Bühlmann's economic premium principle; it is based on general equilibrium theory, a main branch in microeconomics.

Consider a pure exchange market with n agents. Think of the agents as being buyers or sellers of insurance policies. Each agent is characterized by

1. a utility function $u_i(x)$, with $u'_i(x) > 0$ and $u''_i(x) \leq 0$, $i = 1, \dots, n$;
2. an initial wealth w_i , $i = 1, \dots, n$.

Each agent faces an exogenous potential loss according to an individual risk function $X_i(\omega)$, representing the payment due by agent i if state ω occurs. In terms of insurance, $X_i(\omega)$ represents the risk of agent i before (re)insurance. Furthermore, each agent buys a *risk exchange* (see **Default Correlation**) denoted by an individual risk exchange function $Y_i(\omega)$, representing the payment received by agent i if ω occurs. The market price of Y_i is denoted by $\pi[Y_i, \cdot]$. Bühlmann used the concept of a pricing density (pricing kernel, state price deflator) $\varphi : \Omega \rightarrow \mathbb{R}$ so that

$$\pi[Y_i, \cdot] = \int_{\Omega} Y_i(\omega) \varphi(\omega) d\mathbb{P}(\omega) \quad (11)$$

for a fixed probability measure $\mathbb{P}$ on $(\Omega, \mathcal{F})$. An equilibrium is then defined as the pair $(\varphi^*, \mathbf{Y}^*)$ for which:

1.

$$\forall i, \int_{\Omega} u_i \left(w_i - X_i(\omega) + Y_i^*(\omega) - \int_{\Omega} Y_i^*(\omega') \varphi^*(\omega') d\mathbb{P}(\omega') \right) d\mathbb{P}(\omega) \quad (12)$$

maximal for all possible choices of the exchange function $Y_i(\omega)$;

2.

$$\sum_{i=1}^n Y_i^*(\omega) = 0, \quad \forall \omega \in \Omega \quad (13)$$

φ^* is called the *equilibrium pricing density* and $\mathbf{Y}^*$ is called the *equilibrium risk exchange*.

Assume that the utility function of agent i is given by

$$\frac{1}{\alpha_i} (1 - e^{-\alpha_i x}) \quad (14)$$

where $\alpha_i > 0$ denotes the coefficient of absolute risk aversion of agent i and $(1/\alpha_i)$ is his risk tolerance. Solving the equilibrium conditions, Bühlmann obtained the following expression for the equilibrium pricing density:

$$\varphi^*(\omega) = \frac{e^{\alpha Z(\omega)}}{\mathbb{E}[e^{\alpha Z}]}; \quad Z(\omega) = \sum_{i=1}^n X_i(\omega) \quad (15)$$

Equation (15) determines an economic premium principle for any random loss X , namely

$$\pi[X, Z] = \frac{\mathbb{E}[X e^{\alpha Z}]}{\mathbb{E}[e^{\alpha Z}]} \quad (16)$$

Notice that if X and $Z - X$ are independent, a *standard* premium principle is obtained:

$$\begin{aligned} \pi[X, Z] &= \frac{\mathbb{E}[X e^{\alpha X}] \mathbb{E}[e^{\alpha(Z-X)}]}{\mathbb{E}[e^{\alpha X}] \mathbb{E}[e^{\alpha(Z-X)}]} \\ &= \frac{\mathbb{E}[X e^{\alpha X}]}{\mathbb{E}[e^{\alpha X}]} = \pi[X] \end{aligned} \quad (17)$$

This is the time-honored *Esscher premium* (see **Insurance Pricing/Nonlife**). Here, $\frac{1}{\alpha} = \sum_{i=1}^n \frac{1}{\alpha_i}$ can

be interpreted as the risk tolerance of the market as a whole. Note that if the insurance market would contain a large number of agents, the value of $\frac{1}{\alpha} = \sum_{i=1}^n \frac{1}{\alpha_i}$ would be large, or equivalently, the value of α would be close to zero; hence applying the Esscher principle would yield the net premium $\mathbb{E}[X]$.

Remark 3 In equilibrium, only systematic risk requires a risk loading. To see this, suppose that a risk X can be decomposed as follows:

$$X = X_s + X_n \quad (18)$$

where X_s is the systematic risk that is comonotonic with Z , and X_n is the nonsystematic or idiosyncratic risk that is independent of Z (and X_s). Substituting this decomposition in (16), we obtain

$$\pi[X, Z] = \mathbb{E}[X_n] + \frac{\mathbb{E}[X_s e^{\alpha Z}]}{\mathbb{E}[e^{\alpha Z}]} \quad (19)$$

The derived equilibrium coincides with a *Pareto optimal risk exchange* (see **Individual Risk Models**) (Borch [5, 24]).

Bühlmann [25] extended his economic premium principle, allowing general utility functions for market participants. He derived the result that under the weak assumption of concavity of utility functions, equilibrium prices are locally equal to the equilibrium prices derived under the assumption of exponential utility functions. Globally, equilibrium prices are similar, the only difference being that the coefficient of absolute risk aversion is no longer constant, but depends on the agent's individual wealth. The interested reader is referred to Iwaki *et al.* [26] for an extension of the above model to a multiperiod setting. Connections between equations (17) and (7) are studied in Wang [27].

Arbitrage-Free Pricing

In the past decade, we have seen the emergence of a range of financial instruments with underlying risks that are traditionally considered to be “insurance risks”. Examples are catastrophe derivatives and weather derivatives. Such developments on the interface between insurance and finance have put forward questions on appropriate pricing principles for these instruments.

As explained above, traditional actuarial pricing of insurance relies on economic theories of decision

under uncertainty. Financial pricing of contingent claims mainly relies on risk-neutral valuation (see **Equity-Linked Life Insurance; Options and Guarantees in Life Insurance; Risk-Neutral Pricing; Importance and Relevance; Volatility Smile**) and applies an equivalent martingale measure as a risk-adjusted operator; see among many others Duffie [28], Bingham and Kiesel [29], Björk [30], and Protter [31] for textbook treatments. Risk-neutral valuation can be justified within a no-arbitrage setting. For the original work on the relation between the condition of no arbitrage and the existence of an equivalent martingale measure, we refer to Harrison and Kreps [32] and Harrison and Pliska [33]. The basic idea of valuation by adjusting the primary asset process is from Cox and Ross [34]. As is well-known, arbitrage-free pricing may well fit in an equilibrium pricing framework; see e.g., Iwaki *et al.* [26] in an insurance context.

While the no-arbitrage assumption is questionable for traditional insurance markets (see a.o. the discussion in Venter [35, 36] and Albrecht [37]), one may argue that it does hold for insurance products that are traded on the financial markets (securitized insurance risks). Also, especially in life insurance, a significant part of the risk borne is financial risk (interest rate risk, equity risk) rather than pure insurance risk; see e.g., Brennan and Schwartz [38] and Pelsser and Laeven [39]. Arbitrage-free valuation is the natural device for the valuation of the financial portion of the insurance risk portfolio. We focus attention on pure insurance risk.

Several problems arise in applying financial no-arbitrage pricing methodology to securitized insurance risks. The principal problem is that of market incompleteness when the underlying assets are not traded. Indeed, most securitized insurance risks are *index-based* rather than (traded) asset-based. Market incompleteness implies that the contingent claim process cannot be hedged, and therefore no-arbitrage arguments do not, in general, supply a unique equivalent martingale measure for risk-neutral valuation. The problem of market incompleteness proves to be even more serious when insurance processes are assumed to be stochastic jump processes. In the incomplete financial market, there exist an infinite number of equivalent martingale measures and hence, an infinite collection of prices.

The Esscher transform has proven to be a natural candidate and a valuable tool for the pricing of

insurance and financial products. In their seminal work, Gerber and Shiu [40, 41] show that the Esscher transform can be employed to price derivative securities if the logarithms of the underlying asset process follow a stochastic process with stationary and independent increments (Lévy processes). Whereas the Esscher transform of the corresponding actuarial premium principle establishes a change of measure for a random variable, here the Esscher transform is defined more generally as a change of measure for certain stochastic processes. The idea is to choose the Esscher parameter (or in the case of multi assets, the parameter vector) such that the discounted price process of each underlying asset becomes a martingale under the Esscher transformed probability measure. In the case where the equivalent martingale measure is unique, it is obtained by the Esscher transform. In the case where the equivalent martingale measure is not unique (the usual case in insurance), the Esscher transformed probability measure can be justified if there is a representative agent maximizing his expected utility with respect to a power utility function. Inspired by this, Bühlmann *et al.* [42] more generally use *conditional Esscher transforms* to construct equivalent martingale measures for classes of semimartingales; see also Kalssen and Shyriaev [43] and Jacod and Shyriaev [44].

In Goovaerts and Laeven [45], the approach of establishing risk evaluation mechanisms by means of an axiomatic characterization is used to characterize a pricing mechanism that can generate approximate-arbitrage-free financial derivative prices. The price representation derived, involves a probability measure transform that is closely related to the Esscher transform; it is called the *Esscher–Girsanov transform*. In a financial market in which the primary asset price is represented by a general stochastic differential equation, the price mechanism based on the Esscher–Girsanov transform can generate approximate-arbitrage-free financial derivative prices.

We briefly outline below the simple model of Gerber and Shiu [40, 41] for a single primary risk. Assume that there is a stochastic process $\{X(t)\}_{t \geq 0}$ with independent and stationary increments and $X(0) = 0$, such that

$$S(t) = S(0)e^{X(t)}, \quad t \geq 0 \quad (20)$$

Assume, furthermore, that the moment generating function of $X(t)$, denoted by $m_X(\alpha, t)$, exists for all

$\alpha > 0$ and all $t > 0$. Notice that the stochastic process

$$\{e^{\alpha X(t)} m_X(\alpha, 1)^{-t}\}_{t \geq 0} \quad (21)$$

is a positive martingale and can be used to establish a change of probability measure. Gerber and Shiu [40, 41] then define the risk-neutral Esscher measure of parameter α^* such that the process

$$\{e^{-rt} S(t)\}_{t \geq 0} \quad (22)$$

is a martingale with respect to the Esscher measure with parameter α^* ; here r denotes the deterministic risk-free rate of interest. Let us denote the Esscher measure with parameter α by $\mathbb{Q}(\alpha)$ and the true probability measure by $\mathbb{P}$. From the martingale condition

$$\begin{aligned} S(0) &= \mathbb{E}^{\mathbb{Q}(\alpha^*)} [e^{-rt} S(t)] \\ &= \mathbb{E}^{\mathbb{P}} [e^{-rt} e^{\alpha^* X(t)} m_X(\alpha^*, 1)^{-t} S(t)] \end{aligned} \quad (23)$$

we obtain

$$\begin{aligned} e^{rt} &= \mathbb{E}^{\mathbb{P}} [e^{(1+\alpha^*)X(t)} m_X(\alpha^*, 1)^{-t}] \\ &= \left(\frac{m_X(1 + \alpha^*, 1)}{m_X(\alpha^*, 1)} \right)^t \end{aligned} \quad (24)$$

or equivalently

$$\mathbb{E} [e^{(\alpha^*+1)X(1)}] = \mathbb{E} [e^{\alpha^* X(1)+r}] \quad (25)$$

Notice that the parameter α^* is unique since

$$\frac{m_X(1 + \alpha, 1)}{m_X(\alpha, 1)} \quad (26)$$

is strictly increasing in α .

A martingale approach to premium calculation for the special case of compound Poisson processes, the classical risk process in insurance, was studied by Delbaen and Haezendonck [46].

Premium Principles and Their Properties

Many of the (families of) premium principles that emerge from the theories discussed in the section “Classical Theories and Some Generalizations” can be (directly) characterized axiomatically. The general purpose of an axiomatic characterization is to demonstrate what are the essential assumptions to be imposed and what are relevant parameters or concepts to be determined. A premium principle is appropriate if and only if its characterizing axioms are. Axiomatizations can be used not only to justify a premium principle, but also to criticize it.

A systematic study of the properties of premium calculation principles and their axiomatic characterizations was pioneered by Goovaerts *et al.* [9]. We list below various properties that premium principles may (or may not) satisfy.

Properties of Premium Principles

Definition 4 (Law invariance (independence, objectivity)) π is law invariant if $\pi[X] = \pi[Y]$ when $\mathbb{P}[X \leq x] = \mathbb{P}[Y \leq x]$ for all real x .

Law invariance means that for a given risk X , the premium $\pi[X]$ depends on X only *via* the distribution function $\mathbb{P}[X \leq x]$. We note that, to have equal distributions, the random variables X and Y need not, in general, be defined on the same measurable space.

Definition 5 (Monotonicity) π is monotonic if $\pi[X] \leq \pi[Y]$ when $X(\omega) \leq Y(\omega)$ for all $\omega \in \Omega$. π is $\mathbb{P}$ -monotonic if $\pi[X] \leq \pi[Y]$ when $X \leq Y$ $\mathbb{P}$ -almost surely.

Definition 6 (Preserving first-order stochastic dominance (FOSD)) π preserves FOSD if $\pi[X] \leq \pi[Y]$ when $\mathbb{P}[X \leq x] \geq \mathbb{P}[Y \leq x]$ for all $x \in \mathbb{R}$.

Law invariance together with monotonicity implies preserving FOSD.

Definition 7 (Preserving stop-loss (SL) order) π preserves SL order if $\pi[X] \leq \pi[Y]$ when $\mathbb{E}[(X - d)_+] \leq \mathbb{E}[(Y - d)_+]$ for all $d \in \mathbb{R}$.

We note that preserving SL implies preserving FOSD.

It is well known that if the utility function is nondecreasing, which is implied by the monotonicity axiom that is imposed to axiomatize expected utility, then $X \leq_{\text{FOSD}} Y$ implies ordered equivalent utility premiums. If, moreover, the expected utility maximizer is risk-averse, which is equivalent to concavity of the utility function, then $X \leq_{\text{SL}} Y$ implies ordered equivalent utility premiums; see Hadar and Russell [47] and Rothschild and Stiglitz [48] for seminal work on the ordering of risks within the framework of expected utility theory. For an extensive account on stochastic ordering in actuarial science, see Denuit *et al.* [49].

Definition 8 (Risk loading) π induces a risk loading if $\pi[X] \geq \mathbb{E}[X]$.

Definition 9 (Not unjustified) π is not unjustified if $\pi[c] = c$ for all real c .

Definition 10 (No rip off (Nonexcessive loading)) $\pi[X] \leq \text{esssup}[X]$.

Notice that $\mathbb{P}$ -monotonicity implies no rip-off.

Definition 11 (Additivity) π is additive if $\pi[X + Y] = \pi[X] + \pi[Y]$.

The assumption of no-arbitrage implies that the pricing rule is additive.

Definition 12 (Translation invariance (translation equivariance, translativity, consistency)) π is translation invariant if $\pi[X + c] = \pi[X] + c$ for all real c .

Definition 13 (Positive homogeneity (scale invariance, scale equivariance)) π is positively homogeneous if $\pi[aX] = a\pi[X]$ for all $a \geq 0$.

Definition 14 (Subadditivity respectively Super-additivity) π is subadditive (respectively super-additive) if $\pi[X + Y] \leq \pi[X] + \pi[Y]$ (respectively $\pi[X + Y] \geq \pi[X] + \pi[Y]$).

Definition 15 (Convexity) π is convex if $\pi[\alpha X + (1 - \alpha)Y] \leq \alpha\pi[X] + (1 - \alpha)\pi[Y]$ for all $\alpha \in (0, 1)$.

Notice that subadditivity implies convexity. See Deprez and Gerber [50] for an early account of convex premium principles.

Definition 16 (Independent additivity) π is independent additive if $\pi[X + Y] = \pi[X] + \pi[Y]$ when X and Y are independent.

See Gerber [51] and Goovaerts *et al.* [52] for axiomatizations of independent additive premium principles.

Definition 17 (Comonotonic additivity) π is comonotonic additive if $\pi[X + Y] = \pi[X] + \pi[Y]$ when X and Y are comonotonic.

Definition 18 (Iterativity) π is iterative if $\pi[X] = \pi[\pi[X|Y]]$.

In addition to the above-mentioned properties, axiomatic characterizations of premium principles often impose technical (mainly continuity) conditions

required for obtaining mathematical proofs. Such conditions appear in various forms (e.g., if X_n converges weakly to X then $\pi[X_n] \rightarrow \pi[X]$), and are usually difficult to interpret (justify) economically.

A Plethora of Premium Principles

In this section, we list many well-known premium principles and tabulate which of the properties from the section “Properties of Premium Principles” above are satisfied by them (*see Insurance Pricing/Nonlife; Securitization/Life*). The theories presented in the section “Classical Theories and Some Generalizations” are not mutually exclusive. Some premium principles (Esscher) arise from more than one theory. Other premium principles (Dutch) instead are not directly based on any of the above-mentioned theories nor are they based on an axiomatic characterization, but rather on the nice properties that they exhibit.

Definition 19 (Expected value principle) The expected value principle is given by

$$\pi[X] = (1 + \lambda)\mathbb{E}[X], \quad \lambda \geq 0 \quad (27)$$

If $\lambda = 0$, the net premium is obtained. The net premium can be justified as follows: for the risk $X := \sum_{i=1}^n X_i$ of a large homogeneous portfolio, with $X_i \sim \text{iid}$ and $\mathbb{E}[X_i] = \mu$, we have, on the basis of the law of large numbers,

$$\lim_{n \rightarrow \infty} \mathbb{P}[|X - n\mu| < \varepsilon] = 1 \quad (28)$$

for all $\varepsilon > 0$. Hence, in case the net premium μ is charged for each risk transfer X_i , the aggregate premium income $n\mu$ is sufficient to cover X with probability 1.

However, in the expected utility framework, the net premium suffices only for a risk-neutral insurer. Moreover, it follows from ruin theory that if no loading is applied, ruin will occur with certainty. In this spirit, the loading factor λ can be determined by setting sufficiently protective solvency margins. Such solvency margins may be derived from ruin estimates of the underlying risk process over a given period of time; see e.g., Gerber [8] or Kaas *et al.* [53]. This applies in a similar way to some of the premium principles discussed below. For $\lambda > 0$, the loading margin increases with the expected value.

Definition 20 (Equivalent utility (zero utility) principle) See section titled “The Principle of Equivalent Utility”.

Definition 21 (Distortion principle) See section titled “The Principle of Equivalent Utility”.

Definition 22 (Mean value principle) For a given nondecreasing and nonnegative function f on $\mathbb{R}$ the mean value principle is the root of

$$f(\pi) = \mathbb{E}[f(X)] \quad (29)$$

Definition 23 (Variance principle) The variance principle is given by

$$\pi[X] = \mathbb{E}[X] + \lambda \text{Var}[X], \quad \lambda > 0 \quad (30)$$

Definition 24 (Standard deviation principle) The standard deviation principle is given by

$$\pi[X] = \mathbb{E}[X] + \lambda \sqrt{\text{Var}[X]}, \quad \lambda > 0 \quad (31)$$

See Denneberg [54] for critical comments on the standard deviation principle, advocating the use of the absolute deviation rather than the standard deviation. Dynamic versions of the variance and standard deviation principles in an economic environment are studied by Schweizer [55] and Møller [56].

Definition 25 (Exponential principle) The exponential principle is given by

$$\pi[X] = \frac{1}{\alpha} \log \mathbb{E}[\exp(\alpha X)], \quad \alpha > 0 \quad (32)$$

See Gerber [51], Bühlmann [57], Goovaerts *et al.* [52], and Young and Zariphopoulou [58] for axiomatic characterizations and applications of the exponential principle.

Consider a random variable X and a real number $\alpha > 0$, for which $\mathbb{E}[e^{\alpha X}]$ exists. The positive random variable

$$\frac{e^{\alpha X}}{\mathbb{E}[e^{\alpha X}]} \quad (33)$$

with expectation equal to one, can be used as a Radon–Nikodym derivative to establish a change of probability measure. The probability measure obtained thus is called the *Esscher* measure and is *equivalent* to the original probability measure (i.e.,

the probability measures are mutually absolutely continuous). The Esscher transform was first introduced by the Swedish actuary F. Esscher; see Esscher [59].

Definition 26 (Esscher Principle) The Esscher premium is given by

$$\pi[X] = \frac{\mathbb{E}[Xe^{\alpha X}]}{\mathbb{E}[e^{\alpha X}]}, \quad \alpha > 0 \quad (34)$$

As an alternative representation, consider the cumulant generating function (cgf) of a random variable X :

$$\kappa_X(\alpha) := \log(\mathbb{E}[e^{\alpha X}]) \quad (35)$$

The first and second order derivatives of the cgf with respect to α are

$$\kappa'_X(\alpha) = \frac{\mathbb{E}[Xe^{\alpha X}]}{\mathbb{E}[e^{\alpha X}]} \quad (36)$$

and

$$\kappa''_X(\alpha) = \frac{\mathbb{E}[X^2 e^{\alpha X}]}{\mathbb{E}[e^{\alpha X}]} - \left(\frac{\mathbb{E}[Xe^{\alpha X}]}{\mathbb{E}[e^{\alpha X}]} \right)^2 \quad (37)$$

One can interpret $\kappa'_X(\alpha)$ (or the Esscher premium) and $\kappa''_X(\alpha)$ as the mean and the variance of the random variable X under the Esscher transformed probability measure.

Gerber and Goovaerts [60] establish an axiomatic characterization of an independent additive premium principle that involves a mixture of Esscher transforms. A drawback of both the mixed and nonmixed Esscher premium is that it is not monotonic; see Gerber [61] and Van Heerwaarden *et al.* [62]. Goovaerts *et al.* [52] establish an axiomatic characterization of risk measures that are additive for independent random variables, including an axiom that guarantees monotonicity. The premium principle obtained is a mixture of exponential premiums.

Definition 27 (Swiss principle) For a given non-negative and nondecreasing function w on $\mathbb{R}$ and a given parameter $0 \leq p \leq 1$ the Swiss premium is the root of

$$\mathbb{E}[w(X - p\pi)] = w((1 - p)\pi) \quad (38)$$

Notice that the Swiss principle includes both the equivalent utility principle and the mean value

principle as special cases; see Gerber [51], Bühlmann *et al.* [63] and Goovaerts *et al.* [9].

Definition 28 (Dutch principle) The Dutch principle is given by

$$\begin{aligned} \pi[X] &= \mathbb{E}[X] + \theta \mathbb{E}[(X - \alpha \mathbb{E}[X])_+], \quad \alpha \geq 1, \\ 0 &< \theta \leq 1 \end{aligned} \quad (39)$$

The Dutch premium principle was introduced by Van Heerwaarden and Kaas [64].

Definition 29 (Orlicz principle) Let $X \geq 0$. For a given normalized Young function ψ on $\mathbb{R}_+ \cup \{0\}$, the Orlicz premium is the root of

$$\mathbb{E}[\psi(X/\pi)] = 1 \quad (40)$$

The Orlicz principle is a multiplicative alternative to the equivalent utility principle; see Haezendonck and Goovaerts [65].

All premium principles listed in Table 1 are law invariant. All principles are not unjustified, except for the expected value principle with $\lambda > 0$.

A Generalized Markov Inequality

Many of the premium principles discussed above can be derived in a unified approach by minimizing a generalized Markov inequality; see Goovaerts *et al.* [68]. This approach involves two exogenous functions $v(\cdot)$ and $\phi(\cdot, \cdot)$ and an exogenous parameter $\alpha \leq 1$. Assuming that v is nonnegative and nondecreasing and that ϕ satisfies $\phi(x, \pi) \geq 1_{\{x > \pi\}}$, one easily proves the following generalized Markov inequality:

$$\mathbb{P}[X > \pi] \leq \frac{\mathbb{E}[\phi(X, \pi)v(X)]}{\mathbb{E}[v(X)]} \quad (41)$$

We now consider the case where the upper bound in the above inequality reaches a given confidence level $\alpha \leq 1$:

$$\mathbb{P}[X > \pi] \leq \frac{\mathbb{E}[\phi(X, \pi)v(X)]}{\mathbb{E}[v(X)]} = \alpha \leq 1 \quad (42)$$

When $\alpha = 1$, the equation

$$\frac{\mathbb{E}[\phi(X, \pi)v(X)]}{\mathbb{E}[v(X)]} = 1 \quad (43)$$

Table 1 Properties of premium principles

<i>Principle</i>	$M^{(a)}$	$\Pi^{(b)}$	$PH^{(c)}$	$A^{(d)}$	$SA^{(e)}$	$C^{(f)}$	$IA^{(g)}$	$CA^{(h)}$	$SL^{(i)}$	$NR^{(j)}$	$RL^{(k)}$	$I^{(l)}$

Orlicz	+	$-(m)$	+	-	+	+	-	-	+	+	+	-

^(a) M: monotonicity;
^(b) Π : translation invariance;
^(c) PH: positive homogeneity;
^(d) A: additivity;
^(e) SA: subadditivity;
^(f) C: convexity;
^(g) IA: independent additivity;
^(h) CA: comonotonic additivity;
⁽ⁱ⁾ SL: stop-loss order;
^(j) NR: no rip-off;
^(k) RL: nonnegative risk loading;
^(l) I: iterativity.
^(m) The so-called Haezendonck risk measure, which is an extension of the Orlicz premium (see Goovaerts *et al.* [66] and Bellini and Rosazza Gianin [67]), is translation invariant.

Table 2 Premium principles derived from equation (43)

Premium principle	$v(x)$	$\phi(x, \pi)$
Mean value	1	$\frac{f(x)}{f(\pi)}$
Zero utility	1	$\frac{u(\pi - x)}{u(0)}$
Swiss	1	$\frac{w(x - p\pi)}{w((1 - p)\pi)}$
Orlicz	1	$\psi(x/\pi)$

can generate many well-known premium principles; see Table 2.

For all ϕ , v , by equation (42),

$$\pi \geq \inf\{x \in \mathbb{R} : \mathbb{P}[X \leq x] \geq 1 - \alpha\} \quad (44)$$

which sheds light on the relation between premium principles and quantile-based solvency margins.

Pricing of Life Insurance Liabilities

Life insurance policies provide benefits contingent on policyholders' lives. Payouts can be nominally fixed or linked to financial variables, they can embed financial guarantees or allow policyholders to participate in the insurer's profits. We will restrict ourselves to the simplest case of nominally fixed benefits to present the main issues caused by randomness in interest rates and mortality rates. In the section titled "Systematic and Unsystematic Mortality Risk", we begin by distinguishing between systematic and unsystematic mortality risk. We explain why and under what assumptions the number of policies has an impact on the riskiness of an insurer's portfolio. The section titled "Risk Associated with Randomness in Interest Rates" extends the previous section by taking into account the time value of money. The section titled "Risk Associated with Size of Benefits" describes the impact of heterogeneity of sums assured on the riskiness of a portfolio. In the remaining sections, we gradually introduce dynamic considerations into our analysis: in particular, the section titled "Annuities" links randomness in lifetimes with liability duration, while the section titled "Benefits Financed through Regular Premiums" examines the interplay between premiums, accumulation of reserves, and benefit payments. In the section "Random Hazard Rates", we briefly describe how randomness in mortality rates can be modeled dynamically. Finally, we show in the section titled "Pricing of Life Insurance Liabilities" how the risks described in the previous sections can be accounted for when pricing insurance contracts or when placing a market-consistent value on a portfolio of life insurance liabilities.

Systematic and Unsystematic Mortality Risk

We first focus on uncertainty in survival and death rates. Let us consider a portfolio of n insureds at the reference time 0. We are interested in the number of survivors, $N_T(n)$, and in the number of cumulated deaths, $D_T(n) \doteq n - N_T(n)$, up to a fixed future date T (see **Estimation of Mortality Rates**

from Insurance Data). Denoting the random residual lifetimes of the insureds by $\tau^1, \dots, \tau^n$, we need to study the random variable

$$N_T(n) = \sum_{i=1}^n 1_{\{\tau^i > T\}} \quad (1)$$

The symbol 1_A denotes the indicator function of the event A : this means $1_{\{\tau^i > T\}}$ is equal to 1 in case the i th insured is alive at time T and equal to 0 in case of death before T .

If each insured belongs to the same risk class (same age, sex, health status, and type of contract), an insurer can reasonably assume that the random times $\tau^1, \dots, \tau^n$ are *identically distributed*. In particular, the probability of being alive at time T can be expressed as

$$\mathbb{P}(\tau^i > T) = p \quad \text{for all } i \quad (2)$$

with p being a number between 0 and 1.

If the lifetimes $\tau^1, \dots, \tau^n$ can also be assumed to be *independent*, then our random variables $N_T(n)$ and $D_T(n)$ are distributed as binomial random variables with parameters, (n, p) and $(n, 1 - p)$, respectively. When the dimension of the portfolio is large, the law of large numbers applies (see [1]), yielding

$$\lim_{n \rightarrow \infty} \frac{N_T(n)}{n} = E\left(\frac{N_T(n)}{n}\right) = \frac{np}{n} = p \quad (3)$$

where $E(\cdot)$ denotes the expectation operator. By the very same assumptions, we can apply the central limit theorem and obtain

$$\frac{N_T(n)}{n} \sim \text{Normal}\left(p, \frac{p(1-p)}{n}\right) \quad (4)$$

for large enough n . Similar results can be written for the proportion of deaths, $D_T(n)/n$, as n grows larger.

The expressions above have a very intuitive interpretation. They imply that a large enough portfolio of insureds leads to

- higher concentration of actual survivors or deaths around their expected values;
- lower probability of extreme outcomes;
- more bell-shaped distribution of survivors and deaths.

If we denote the actual number of survivors at time T by n_T , the risk of n_T being different from $E(N_T(n)) = np$ is called "risk of random

fluctuations” around the expected value, or “process risk” (see [2, 3]). According to equations (3, 4) such risk can be reduced by pooling together a large enough number of individuals, and hence the name *pooling risk* (see **Model Risk**). This risk reduction is based on the fact that fluctuations of outcomes around the mean tend to offset each other for a large enough portfolio: such risk is then an example of *unsystematic risk*, in the sense that it affects different individuals in no systematic way. If we measure risk in terms of standard deviation ($\sigma(\cdot)$), we see from equation (4) that risk reduces at a lower pace than the increase in portfolio dimension, since

$$\lim_{n \rightarrow \infty} \sigma \left(\frac{N_T(n)}{n} \right) = \lim_{n \rightarrow \infty} \sqrt{\frac{p(1-p)}{n}} = 0 \quad (5)$$

As a consequence, the reduction in risk is only of order $\sqrt{n}$. Things become worse if we relax some of the assumptions made so far.

For example, we have assumed that the probability of surviving at time T is well known at contract inception and equal to a deterministic number p . In practice, this approach may be inadequate for two reasons. First, the insurer has no complete knowledge of the risk factors affecting policyholders’ lifetimes, so that it may desirable to have a model allowing for some unobservable variables. Second, the evolution of mortality is a complex nonstationary phenomenon, whose long-term modeling is heavily subject to model/parameter uncertainty. Depending on the specific types of contracts considered and on the length of the time horizon T , the previous caveats can become extremely relevant. If we explicitly allow for randomness in the key parameter p , then things change radically. As an example, assume that $N_T(n)$ depends on a random variable X that cannot be fully known before time T . Keeping the assumption of identical distribution of $\tau^1, \dots, \tau^n$, expression (2) can now be rewritten as

$$\mathbb{P}(\tau^i > T|X) = p(X) \quad \text{for all } i \quad (6)$$

where $p(\cdot)$ is a function of X taking values between 0 and 1. In this case, the lifetimes $\tau^1, \dots, \tau^n$ are no longer independent: the common factor X affects the probability of survival at time T of each insured in the portfolio. We thus say that X represents a *systematic risk*.

The question now is, in the present setup, can we still benefit from the limiting results in equations

(3, 4) we saw in the case of fully known p ? Only to a very limited extent, as we now show. First, if X can be truly thought of as the only risk factor commonly affecting the likelihood of death of the n individuals, we can assume that $\tau^1, \dots, \tau^n$ are *conditionally independent*, given knowledge of X . Second, if we take as fixed a realization x of X , we can exploit the independence and identical distribution of $\tau^1, \dots, \tau^n$ to repeat the reasoning developed in the deterministic case and obtain expression (4) with p replaced by $p(x)$. Thus, the nice properties associated with the law of large numbers and the central limit theorem can now hold only conditional on the value taken by X . Let us see what happens unconditionally instead. From equation (6), by iterating expectations we obtain

$$\mathbb{P}(\tau^i > T) = E(\mathbb{P}(\tau^i > T|X)) = E(p(X)) \quad (7)$$

$$E(N_T(n)) = E(E(N_T(n)|X)) = nE(p(X)) \quad (8)$$

and thus what used to be a given probability is now replaced by the estimate $E(p(X))$. Furthermore, the variance of $N_T(n)$ can now be expressed as follows:

$$\begin{aligned} V(N_T(n)) &= V(E(N_T(n)|X)) + E(V(N_T(n)|X)) \\ &= n^2 V(p(X)) + nE(p(X)(1-p(X))) \end{aligned} \quad (9)$$

where we have used the representation property of variances (see [1]) and the fact that conditional on X , $N_T(n)$ is binomially distributed with parameters $(n, p(X))$. From equation (9), it is easily seen that the standard deviation of $N_T(n)/n$ does not go to zero as n grows larger, since

$$\begin{aligned} \lim_{n \rightarrow \infty} \sigma \left(\frac{N_T(n)}{n} \right) &= \lim_{n \rightarrow \infty} \sqrt{V(p(X)) + \frac{E(p(X)(1-p(X)))}{n}} \\ &= \sigma(p(X)) \end{aligned} \quad (10)$$

As a consequence, no matter how large the portfolio, there always remains an undiversifiable risk component induced by X .

Risk Associated with Randomness in Interest Rates

In the simple portfolio model of the previous section, we simply considered the distribution of the number of survivors (or cumulated deaths) at some future date T . We now introduce monetary benefits and focus on the simple case in which each survivor is entitled to a payment equal to one monetary unit upon survival at T . This means the portfolio of n individuals entails a random liability equal to $N_T(n)$ monetary units at time T . To express it in current money terms, we need to take into account the time value of money.

Suppose that it is possible to deposit cash in a bank account obtaining an instantaneous return equal to a constant $r > 0$. We can thus generate e^{rT} units of money at the final date T by investing one unit at time 0 and continuously reinvesting the proceeds up to time T . If we go back to our portfolio, we can now express the survival benefits in current money terms as

$$e^{-rT} 1_{\{\tau^1 > T\}}, \dots, e^{-rT} 1_{\{\tau^n > T\}} \quad (11)$$

Since each random variable in equation (11) is scaled by a deterministic factor e^{-rT} , the analysis of risk made in the previous section carries over without modifications.

The assumption of a constant interest rate may be quite unrealistic, particularly when the time horizon T is long or if the setup is extended to benefits embedding interest rate guarantees or linked to other financial variables. Let us assume that at each time $t \geq 0$ the risk-free rate is a random variable r_t . The amount of money we can get at time T from depositing 1 in the bank account at 0 and rolling over the proceeds up to T is now a random variable, $e^{\int_0^T r_s ds}$. The present value of the survival benefits as in equation (11) must now be changed accordingly as follows:

$$e^{-\int_0^T r_s ds} 1_{\{\tau^1 > T\}}, \dots, e^{-\int_0^T r_s ds} 1_{\{\tau^n > T\}} \quad (12)$$

The risk exposure is now different from equation (11), because the quantity $e^{-\int_0^T r_s ds}$ represents a common risk factor simultaneously affecting the present value of the benefits payable to each policyholder. For example, if the realization of interest rates from 0 to T takes values lower than the constant r considered in equation (11), then each liability in equation (12)

is higher than the corresponding one in equation (11), independently of the specific policyholder considered.

Risk Associated with Size of Benefits

We have seen that the independence assumption plays a crucial role in allowing the insurer to reduce risk by pooling together several contracts. The hypothesis of identical distribution is also relevant and should not be taken for granted. To show its impact on the portfolio risk exposure, we examine the case of policyholders with similar biometric characteristics taking out the same type of contract but with different levels of benefits.

As a simple example, consider a one-period term assurance providing a benefit C^i at time T upon death of policyholder i between time 0 and T . All residual life times $\tau^1, \dots, \tau^n$ are assumed independent and identically distributed. The random present values of the benefits,

$$e^{-\int_0^T r_s ds} C^1 1_{\{\tau^1 \leq T\}}, \dots, e^{-\int_0^T r_s ds} C^n 1_{\{\tau^n \leq T\}} \quad (13)$$

give rise to the aggregate liability

$$H = e^{-\int_0^T r_s ds} \sum_{i=1}^n C^i 1_{\tau^i \leq T} \quad (14)$$

Let $\bar{C}$ and $\bar{C}^{(2)}$ represent the mean and the second moment of the sums assured:

$$\bar{C} \doteq \frac{\sum_{i=1}^n C_i}{n} \quad \bar{C}^{(2)} \doteq \frac{\sum_{i=1}^n C_i^2}{n} \quad (15)$$

Without loss of generality, we can assume zero interest rates and compute the expected value and variance of equation (14) as follows:

$$E(H) = n(1-p)\bar{C} \quad (16)$$

$$\begin{aligned} V(H) &= n(1-p)p\bar{C}^{(2)} \\ &= n(1-p)p(\bar{C}^2 + V(C)) \end{aligned} \quad (17)$$

with p defined by equation (2). From the second equality in equation (17), we can see that for fixed $\bar{C}$, the variance of the random liability H is minimal when $V(C) = 0$, i.e., when the insureds are homogeneous not only in terms of mortality risk but also

in terms of sums assured. Additional insights can be gathered by computing the coefficient of variation of H , $\sigma(H)/E(H)$, a quantity measuring the degree of dispersion of the distribution of H . Exploiting the first equality in equation (17), we obtain

$$\frac{\sigma(H)}{E(H)} = \sqrt{\frac{p}{1-p}} \frac{\sqrt{\bar{C}^{(2)}}}{\sqrt{n} \bar{C}} \quad (18)$$

which is increasing in $\bar{C}^{(2)}$ for fixed average sum assured $\bar{C}$ and portfolio dimension n . When $C_i = C$ for all i , the expression above reduces to

$$\frac{\sigma(H)}{E(H)} = \sqrt{\frac{p}{1-p}} \frac{1}{\sqrt{n}} \xrightarrow{n \rightarrow \infty} 0 \quad (19)$$

showing that risk can be reduced by increasing the dimension of the portfolio and that the convergence to 0 is of order $\sqrt{n}$ as observed in the section named “Systematic and Unsystematic Mortality Risk”. On the other hand, if one of the n sums assured is large enough, we have $\sqrt{\sum_{i=1}^n C_i^2} / \sum_{i=1}^n C_i \cong 1$ and thus equation (18) becomes

$$\frac{\sigma(H)}{E(H)} = \sqrt{\frac{p}{1-p}} \frac{\sqrt{\sum_{i=1}^n C_i^2}}{\sum_{i=1}^n C_i} \cong \sqrt{\frac{p}{1-p}} \quad (20)$$

showing that the pooling effect is completely prevented by the presence of a single outlier.

Risk Associated with Timing of Benefit Payments

So far we have considered liabilities involving survival benefits payable at a given fixed time. We extend this basic case in two directions: survival benefits payable until death (annuities) and benefits financed by premiums payable over time. In the following text, τ will represent the random residual life time of a generic policyholder (*see Risk Classification/Life*).

Annuities

An annuity is a contract providing a guaranteed stream of regular (e.g., monthly) payments contingent on survival of the policyholder. As an example, consider a contract paying a unitary rate continuously

until death. In current money terms, the stream of benefits is given by the following random variable:

$$\int_0^\tau e^{-\int_0^t r_s ds} dt \quad (21)$$

If the short rate is equal to zero, we can see immediately that equation (21) coincides with the insured’s life expectancy, $E(\tau)$. As a consequence, the longer the life expectancy of the policyholder, the higher the expected liabilities faced by the insurer. In the more general case of nonzero interest rates, an increase in life expectancy leads to an increase in the *duration* of liabilities and hence in the exposure to interest rate movements.

Benefits Financed through Regular Premiums

As in the section titled “Risk Associated with Randomness in Interest Rates”, let us consider a term assurance providing a benefit C in case of death between 0 and T , but suppose now that the benefit is paid at τ rather than at T . The random present value of the benefit is given by

$$e^{-\int_0^\tau r_s ds} C 1_{\{\tau \leq T\}} \quad (22)$$

In exchange for this cover, the insurer could require the policyholder to pay a premium rate $\pi(\cdot)$ continuously over time. Pricing issues are examined in detail in the section titled “Pricing of Life Insurance Liabilities”: for the moment, we can just suppose that the insurer is risk-neutral and that $\pi(\cdot)$ is a function leading to *equivalence*, in current money terms, between the cumulated cashflows from the insurer to the policyholder and those from the policyholder to the insurer. In other words, the following must hold at time 0:

$$\begin{aligned} E \left(\int_0^\tau e^{-\int_0^s r_u du} \pi(s) 1_{\{\tau > s\}} ds \right) \\ = E \left(e^{-\int_0^\tau r_u du} C 1_{\{\tau \leq T\}} \right) \end{aligned} \quad (23)$$

Besides equation (23), additional requirements (see below) are imposed to determine an optimal rate $\pi(\cdot)$. Only in the case of a constant premium rate $\pi(\cdot) \equiv \bar{\pi}$, equation (23) is enough to determine $\bar{\pi}$ uniquely.

Once a $\pi(\cdot)$ satisfying equation (23) is fixed, the equivalence equation does not necessarily hold at any generic time t following 0. Indeed, we have

$$\begin{aligned} V_t + E_t \left(\int_t^T e^{-\int_t^s r_u du} \pi(s) 1_{\{\tau > s\}} ds \right) \\ = E_t \left(e^{-\int_t^\tau r_u du} C 1_{\{t < \tau \leq T\}} \right) \end{aligned} \quad (24)$$

where $E_t(\cdot)$ denotes conditional expectation, given the information available at time t . The balancing term V_t makes sure that equality holds in equation (24) and is better understood if we rearrange equation (24) to obtain

$$\begin{aligned} V_t = E_t \left(e^{-\int_t^\tau r_u du} C 1_{\{t < \tau \leq T\}} \right. \\ \left. - \int_t^T e^{-\int_t^s r_u du} \pi(s) 1_{\{\tau > s\}} ds \right) \end{aligned} \quad (25)$$

so that V_t represents the time- t expected present value of the net outstanding liabilities. V_t is called *prospective reserve* of the contract, because it quantifies the funds needed to meet the insurer's liabilities from time t onward. Usually $\pi(\cdot)$ is chosen so as to make sure that at each $t \in [0, T]$ V_t is nonnegative with a high level of confidence. In other words, $\pi(\cdot)$ ensures that at each future date the expected present value of future benefits is larger than the remaining premiums to be paid. This guarantees that the policyholder is locked into a debt position and has no obvious incentives to walk away from the contract. Another important consequence is that premiums “anticipate” benefits (in expected present value terms) and an adequate investment return can be earned on the reserves before benefits are paid out.

The mechanism through which individual premiums lead to the creation of reserves to support benefit payments relies once again on the pooling of several independent homogeneous risks. Indeed, equation (24) simply relies on expected values: only a large portfolio of policyholders can ensure that, on average, the reserves “released” from those who die plus the premiums from those who survive are enough to pay off benefits and to set aside the reserves needed for the insureds remaining in the portfolio. Again, if the portfolio is not large enough, random fluctuations can lead to insufficient aggregate reserves

and force the insurer to inject capital in the portfolio. But now, contrary to the cases studied before, it is not only the level of deaths (higher or lower than expected) that matters, but also their timing. Indeed, benefit payouts occurring earlier than expected entail more risk than those occurring later, because they deplete reserves and reduce investment income to be earned on them (see [2, 4, 5]).

Random Hazard Rates

The previous sections have gradually introduced dynamic considerations into the analysis of risks affecting life insurance policies. In the same way that interest rates can randomly evolve over time, it is now natural to allow for uncertainty in the evolution of survival probabilities and death rates. One way of doing so is by modeling the likelihood of survival at each time t as a random variable (here we follow [6, 7]; see [8] for a survey of dynamic mortality models). Specifically, for a generic τ we can set

$$\mathbb{P}(\tau > t | \mathcal{F}_t) = e^{-\Gamma_t} \quad (26)$$

where Γ is a nondecreasing process starting from $\Gamma_0 = 0$ and $\mathcal{F}_t$ represents information about the evolution of Γ (but not about the actual occurrence of τ) up to time t . Under these assumptions, the process in equation (26) takes values between 0 and 1 and is decreasing with t , which is exactly what we need to model each point of the survival function of τ as a random variable.

Going back to the portfolio of the section titled “Systematic and Unsystematic Mortality Risk”, suppose that the policyholder's life times $\tau^1, \dots, \tau^n$ are conditionally independent, given Γ_T , and all with the same likelihood of survival as in equation (26). It then follows that $N_T(n)$ is conditionally binomial with parameters $(n, e^{-\Gamma_T})$ and we have, for example,

$$E(N_T(n) | \mathcal{F}_T) = \sum_{i=1}^n \mathbb{P}(\tau^i > T | \mathcal{F}_T) = ne^{-\Gamma_T} \quad (27)$$

If we set $X \doteq \Gamma_T$, from equation (26) we obtain exactly equation (6) with $p(X) = e^{-X}$, so that Γ represents a source of undiversifiable risk as explained in the section titled “Systematic and Unsystematic Mortality Risk”. The advantage of the present setup is that we need not fix our attention on a single date T nor on a “static” risk factor X . Also, we can easily obtain

stochastic counterparts of key actuarial quantities. For example, assume that Γ can be expressed as

$$\Gamma_t = \int_0^t \mu_s ds \quad (28)$$

for some nonnegative process μ . Under suitable assumptions (e.g., when $1_{\{\tau \leq t\}}$ is the first jump of a Cox process), μ can be identified with the random intensity of mortality of the insured (see [7] for details). This means that μ_t can be seen as the time- t instantaneous conditional death probability of an individual. Also, by using equations (26, 28) and iterating expectations we can write

$$\mathbb{P}(\tau > T) = E(\mathbb{P}(\tau > T | \mathcal{F}_T)) = E\left(e^{-\int_0^T \mu_s ds}\right) \quad (29)$$

where we recognize (apart from the expectation) the usual expression for survival probabilities one finds in standard actuarial textbooks (e.g., [4]). More useful implications become apparent when it comes to analyzing financial and demographic risks in an integrated and dynamic fashion. As an example, consider the benefits paid by the term assurance of section titled “Benefits Financed through Regular Premiums”. Under equation (28), the expected value of equation (22) takes the form

$$E\left(\int_0^T e^{-\int_0^t (r_s + \mu_s) ds} C \mu_t dt\right) \quad (30)$$

which can be easily computed via simulation, or even analytically, if r and μ are chosen within a suitable class of processes (see [6, 7, 9, 10]). The probabilistic framework described in this section can be used to extend any static, traditional demographic model to a dynamic setting (e.g., [11]). An extension to multiple cohorts of insureds is studied in [12]. Dealing with expressions like equation (30) is what is most needed when pricing life insurance liabilities, as we show in the next section.

Pricing of Life Insurance Liabilities

In the section titled “Benefits Financed through Regular Premiums”, we have seen how premiums could be computed through the equivalence principle in the case of a risk-neutral insurer. In practice, the equivalence principle is used under a probability measure $\tilde{\mathbb{P}}$ different from $\mathbb{P}$, in order to reflect risk

aversion: $\tilde{\mathbb{P}}$ is suitably *favorable* to the insurer, in that it embeds a profit loading providing compensation for the different types of risks taken on by the insurer.

The choice of $\tilde{\mathbb{P}}$ is generically said to be driven by *prudence*: the latter is defined in different ways, e.g., as the ability to generate profits over time or to maintain the company solvent with a sufficiently high probability. Since we have already introduced prospective reserves in the section titled “Benefits Financed through Regular Premiums”, it is natural to define prudence in terms of reserves computed under different probability measures. We say that a measure $\tilde{\mathbb{P}}$ is prudent if the valuation of the net liabilities under $\tilde{\mathbb{P}}$ is greater than what we would obtain by employing the objective (realistic) measure $\mathbb{P}$ (e.g., [4, 5, 13, 14]). In other words, this is true if

$$\tilde{V}_t \geq V_t \quad \text{for all } t \quad (31)$$

where we have extended the notation introduced in the section titled “Benefits Financed through Regular Premiums” to reserves computed under different probability measures. In particular, $\tilde{V}_t$ is obtained by taking expectation under $\tilde{\mathbb{P}}$ in equation (25).

Condition (31) shows that $\tilde{\mathbb{P}}$ is pessimistic enough to overestimate the insurer’s net liabilities at each point in time. This involves setting aside a larger amount of funds upon which to earn an adequate return to pay out benefits more comfortably. Of course, there is a trade-off, in that premiums are in the end determined by the interaction of the risk preferences of both the insurer and the policyholder.

From a capital markets perspective, insurance securities should be priced exactly as any other financial security. In a frictionless competitive market, prices should satisfy the principle of no-arbitrage, meaning that no sure profit can be realized at zero cost (see [15] for the general theory and detailed references). If the market is complete, any random payoff can be replicated by suitably trading in the available assets, and the no-arbitrage price of a security is uniquely determined by the cost of setting up the strategy that hedges the security’s payoffs. When markets are incomplete, prices may not uniquely determined anymore. Indeed, there may exist an entire interval of prices consistent with no-arbitrage and the exact price chosen depends on the risk preferences of market participants.

Life insurance markets are an example of incomplete markets for the following reasons: they involve

exposures to risk factors (mortality) that are typically not spanned by financial securities; they are sometimes very long term, so that some financial risks (e.g., long-term interest rates) are not fully spanned by traded securities; finally, they are subject to trading constraints, in that insureds only take long positions on insurance contracts and there is no liquid secondary market for insurance contracts.

From a technical point of view, no-arbitrage ensures essentially the existence of a probability measure $\mathbb{P}^*$ *equivalent* (i.e., agreeing on the sets of null probability) to $\mathbb{P}$ under which security prices grow on average at the risk-free rate. Stated another way, security prices can be computed by employing the discounted cashflow approach, with discount rate r and probability $\mathbb{P}^*$. Market completeness translates into uniqueness of $\mathbb{P}^*$, while incomplete markets entail the existence of infinitely many such equivalent probabilities, each of them reflecting different risk preferences. This perspective can be fruitfully employed in the context of insurance pricing, which we have already discussed, and of market consistent valuation of insurance liabilities. The latter is required by some accounting standards and is based on the idea that the fair value of a portfolio of insurance liabilities should be equal to the hypothetical price that another insurer would pay to take them over if a liquid secondary market existed. Under the setup introduced in the section “Random Hazard Rates”, all probability measures equivalent to $\mathbb{P}$ can be parameterized by a couple of processes (η, ϕ) (with ϕ strictly positive) playing different roles in reflecting an agent’s risk aversion (see [7]). As a result, we can recast insurance pricing and market-consistent valuation in a unified framework by setting $\tilde{\mathbb{P}} \doteq \mathbb{P}^{(\tilde{\eta}, \tilde{\phi})}$ and $\mathbb{P}^* \doteq \mathbb{P}^{(\eta^*, \phi^*)}$. The two probabilities may coincide in special cases: we will now focus on $\tilde{\mathbb{P}}$ for ease of notation.

The processes $\tilde{\eta}$ and $\tilde{\phi}$ arise in the following way: $\tilde{\eta}$ contributes to the change of probability measure by entering the dynamics of the systematic risk sources (for example, interest rates and intensity of mortality); $\tilde{\phi}$ enters the change of measure through the survival indicators $1_{\{\tau^1 > t\}}, \dots, 1_{\{\tau^n > t\}}$ of the policyholders in the portfolio. In terms of risk adjustments, $\tilde{\eta}$ introduces a conservative adjustment in the random evolution of the systematic sources of risk, while $\tilde{\phi}$ may induce a change in the intensity of mortality itself, in the sense that the intensity of mortality

under $\tilde{\mathbb{P}}$ is given by $\tilde{\mu} = \tilde{\phi}\mu$ (see [7] for details). The meaning of the risk adjustments is then the following: $\tilde{\eta}$ adjusts for systematic sources of risk, and $\tilde{\phi}$ for the unsystematic risk of random fluctuations in the jumps of $1_{\{\tau^1 > t\}}, \dots, 1_{\{\tau^n > t\}}$, once the systematic risk factors have been taken into account (see discussion in the section titled “Systematic and Unsystematic Mortality Risk” and expressions (6, 7, 9)). For all this to make sense, the crucial assumption of conditional independence of $\tau^1, \dots, \tau^n$ must be satisfied. As a consequence, we may see $\tilde{\phi}$ as accounting for the risk that the systematic risk factors may not encompass all sources of risk commonly affecting the random lifetimes $\tau^1, \dots, \tau^n$.

As a concrete example, let us consider the case of a single premium term assurance providing the benefit as in equation (22). The single premium, Π , can be expressed as

$$\Pi = \tilde{E} \left(e^{-\int_0^T r_s ds} C 1_{\{\tau \leq T\}} \right) \quad (32)$$

for suitable $\tilde{\mathbb{P}}$. In the random hazard rate setup of the previous section and under some technical conditions, the previous expression can be rewritten as

$$\begin{aligned} \Pi &= \tilde{E} \left(\int_0^T e^{-\int_0^t (r_s + \tilde{\mu}_s) ds} C \tilde{\mu}_t dt \right) \\ &= \tilde{E} \left(\int_0^T e^{-\int_0^t (r_s + \tilde{\phi}_s \mu_s) ds} C \tilde{\phi}_s \mu_t dt \right) \end{aligned} \quad (33)$$

which shows the way in which risk aversion is encapsulated in the pricing mechanism: by taking expectation under a probability measure different from $\mathbb{P}$ and by adjusting the intensity of mortality (unless $\phi^* \equiv 1$). From equation (33), we see that $\tilde{\phi}$ adjusts the sum assured C as well: it can thus capture aversion to the risks described in the section titled “Risk Associated with Size of Benefits”.

What we have described so far is a coherent pricing structure, but the key point is to specify $(\tilde{\eta}, \tilde{\phi})$. A common approach is to fix some optimality criterion (e.g., expected utility maximization) and determine the risk premiums associated with the trading strategies solving the optimization problem. This can be done fairly explicitly in a few cases. For example, in [10, 16] liabilities are priced by identifying the initial price of the so-called risk-minimizing strategies. These are trading strategies that allow to perfectly replicate a liability payoff, while minimizing

the fluctuations in costs to be incurred over time to sustain the strategy. They typically embed risk aversion to systematic risk ($\tilde{\eta} \neq 0$), but risk neutrality to other risks ($\tilde{\phi} \equiv 1$). In practice, insurers have a range of requirements to fulfill when optimally designing and pricing complex contracts. Simulation and iterative optimization procedures are therefore utilized to come up with adequate risk margins.

When more emphasis is laid on market-consistent accounting of liabilities, it is natural to investigate how the above framework translates the risk preferences inherent in prices and assumptions used in the insurance market. Some results are provided in [7, 17], where the authors calibrate $(\tilde{\eta}, \tilde{\phi})$ and recover the risk premiums implied by different annuity markets.

To conclude, we mention two additional recent contributions. In [18], liabilities are priced by adopting the principle of equivalent utility, i.e., by setting a price that leaves the insurer indifferent between accepting or refusing a liability according to a given utility function. In [19], liabilities are priced by setting a target instantaneous Sharpe ratio. In both cases, under suitable assumptions nonzero risk premiums for systematic and unsystematic risk can be identified.

Privacy Protection in an Era of Data Mining and Record Keeping

Even though it is not guaranteed explicitly by the US constitution, the “right to privacy” is seen by many individuals as fundamental. There is widespread, and in some cases well-founded, fear of misuse of personal information (about one’s activities, associates, economic status, and health, for instance) by governments, organizations – for example, current or potential employers, and other individuals. Multiple factors currently exacerbate these fears: the legitimate need of governments for information, the near-complete reliance on electronic technologies to assemble, transmit, and store information, and the scope of the information collected: where one goes, what one eats, what one reads, with whom one associates and the footprint of one’s house all end up in someone’s database, not always accurately. Use of information for purposes other than that for which it was obtained has become rampant.

In this article, we provide a framework for thinking about privacy protection in an era of data mining and record keeping, and discuss approaches to the problem. While there are also important issues of organizational privacy – the protection of not simply proprietary information and trade secrets, but also economic information and information about employees, the focus is on personal privacy. It is also focused on the United States, which often lags behind the European Community in terms of protecting privacy.

Not uniquely, but possibly most visibly, privacy protection is where competing risks collide.

Background

By any standard, privacy (*see* **Syndromic Surveillance; Public Health Surveillance**) is an illusive concept. Physical privacy – protection of one’s person and home from “unreasonable searches and seizures” is articulated in Amendment IV to the US Constitution and well established legally. Breaches are for the most part readily detectable. Recourse is possible. None of these is true for information privacy. Few people know or have any meaningful

capability to detect or monitor who or which organizations hold what information about them, whether that information is correct, or for what purposes it is used, which may be entirely different from those for which it was collected. The threats are so diverse that new terms, such as *identity theft* have been coined to describe them.

The US Congress has reacted to some perceived and real threats to information privacy. Notable among congressional actions are the Fair Credit Reporting Act (1971)^a and the Health Insurance Portability and Accountability Act (HIPAA), enacted in 1996. Social security numbers cannot be used as identifiers, and have been removed from driver’s licenses and many databases.

Despite these actions, the public’s sense is that threats to information privacy are increasing rather than diminishing. Near-daily reports of intrusions into corporate databases containing credit card or other information add to the concerns.

What are the Risks and Impacts?

For an individual, there are seemingly evident risks associated with sensitive information being “in the wrong hands.” These risks are widely perceived as increasing. The most dramatic change over the past 5 years is not collection of the information, but rather its ready *accessibility* on the World Wide Web. More than 80% of the people in the United States are identified uniquely by their date of birth, gender, and five-digit ZIP code. Finding this information about someone on the web takes only a few minutes, using public sources such as voter registration and property ownership databases, and commercial services.

How real are the risks, and what are the consequences? Some risks, for instance, identity theft and being denied employment on the basis of medical conditions, are both real and carry severe, material consequences. Other risks are more nebulous. For instance, what is the risk associated with a third person knowing one’s salary, how much one’s house is worth, or what one has recently purchased online? And what are the consequences, other than the person’s knowing something one would prefer him or her not to know, if that information is acted on in a way that harms one?

One legal response is to remove consideration of harm. For some time, information collected by US “official statistics” agencies such as the Census

Bureau has been protected by law. Disclosure of identifiable information by employees is a felony. The disclosure is a crime in itself. The veracity of the information, which would protect disclosers under libel law, is also immaterial.

Although less widely recognized, there are also significant risks associated with incorrect information about individuals. Visible instances include people who have been unable to board airplanes because of the similarity of their names to those on “do not fly” lists and mistakes in medical treatment. Invisible instances are surely more numerous, and largely uncharacterized. Arguably, many people are at more risk from low-quality information (*see Managing Infrastructure Reliability, Safety, and Security; Human Reliability Assessment; Meta-Analysis in Nonclinical Risk Assessment*) about them than from correct information about them.

A final, especially invidious risk associated with information privacy is not knowing who has had access to what information. Moreover, information is not a consumable, and can be accessed an unlimited number of times.

From a social perspective, things are more complicated. The defining events for much of the current discussion about privacy are the terrorist attacks of September 11, 2001. The immense amount of information assembled *ex post facto* about the attackers and their internal and external interactions poses central questions: (a) Could this information have been used to prevent the attacks? (b) At what cost, not only financial, but also in terms of individual rights and liberties would this have been achieved? (c) What would be the recourse for those falsely suspected or accused? In the United States at least, the fact that the federal government has not always been (seen as) a responsible protector of information compounds the issues.

The impacts of the government’s knowing too little, from either a national security or policy perspective (What if the FDA had insufficient information to detect harmful drugs?) are obviously real. When the government has been at risk of having too little information, the Congress has often acted: examples include the USA Patriot Act [1] (which is controversial with respect to existence and implementation) and mandatory reporting of drug side effects. Less attention has been paid to information quality issues. One exception is the Fair Credit Reporting

Act, which provides individuals the ability to access and correct their credit records.

Individuals hold disparate views of the risks and impacts of the government’s knowing too much about its citizens. A significant complication, as discussed previously, is that “having access to information” and “causing harm from information” are quite different. Extreme liberals and conservatives argue, for very different reasons, that possession of information by the government is inherently bad. The prevailing view, however, seems to be more pragmatic – that governments can be trusted not to misuse information.

Governments are not the only organizations relevant to privacy. Organizations from e-tailors to insurance companies to universities assemble, hold and in some cases share or sell information about their customers or employees. Paradoxes abound. Students’ records have been protected since the Family Education Rights and Privacy Act (FERPA) was passed in 1974, while medical records received significant protection much more recently (HIPAA, 1996)^b. Customers of grocery and other stores readily surrender information about their buying habits in return for discounts. Web site “privacy policies” vary wildly. Much information about individuals is provided to the government by their employers. So, no one can answer confidently the question “Who knows what (true or false) about me?”

Nor are the mega problems the only ones. Researchers generate (for example, in medical and sociological studies) data containing sensitive information. At the same time, there are pressures to share data (e.g., for scientific verification), especially if public funds were used to generate them. Official statistics agencies wish to make their data available to researchers and policy makers: their data warehouses are not meant to be data cemeteries.

The Trade-offs

As noted in the section titled “Background”, privacy and information is a context in which risks inevitably compete, at least with respect to governments. There are conflicting, possibly irreconcilable, pressures. Beyond the use of census data for congressional apportionment – the census is prescribed by the US Constitution, the right of the government to collect information for use in setting policy and enforcing statutes is well established. The same is true of

information collected to preserve national security. In many settings, there are prohibitions against use of such information for other purposes.

There is, however, one significant difference between national security and official statistics: information provided to official statistics agencies is almost always provided knowingly, while information collected for national security may be obtained in a clandestine manner.

In part, the trade-offs are classical ones between individual risk and social benefit: more knowledge on the part of (a responsible) government engenders privacy risks to individuals, but leads to societal benefit. As might be expected, society's position on these trade-offs is ambivalent. To a degree that some consider remarkable, the US citizenry has been willing to surrender personal information in the name of national security. Nearly everyone responds to the census, and in the overwhelming majority of cases, responds accurately. At the same time, there is profound discomfort with the potential for abuse.

Trade-offs between individual privacy and societal benefit are not new. Those who pay taxes or serve in the armed forces relinquish their privacy. So do those who enroll in public schools, or receive economic assistance from the government. What distinguishes information privacy is that it can be given up involuntarily, unwittingly, and infinitely often, and that the information may be incorrect.

Proposed Solutions

There is no shortage of proposals for strengthening privacy protection in today's world. At a very high level, these can be grouped into *behavioral solutions*, *policy-driven solutions*, and *technological solutions*. Naturally, the lines between them are blurred and any effective long-term strategy must involve all three.

Behavioral solutions seek to make individuals aware of privacy issues, so that even in the absence of institutional safeguards, they can take as many steps as possible. Examples include verifying the legitimacy of those conducting government surveys, protecting credit cards from prying eyes, and not writing down computer passwords. But despite attention to privacy in the media and the ease of being (at least somewhat) safe, naïveté and carelessness remain rampant.

Policy-driven solutions are government-directed means by which individuals can protect their privacy.

Examples include being able to access and amend one's own records. A stronger version would be notification of who had accessed one's records, when, and for what purpose. Many organizations require computer users to use "strong" passwords and to change them frequently. Some policy-driven solutions go further, forbidding acts that an individual might not be aware of; FERPA and HIPPA are examples.

Technological solutions are meant to counter threats electronically. Encryption protects data from authorized access. Techniques for authenticating computer users are increasingly powerful. Water-marking may be able to trace improperly shared information. Two active and closely related fields – *privacy-preserving data mining* in [2] computer science and *statistical disclosure limitation* (SDL) (see [3, 4] **Near-Miss Management: A Participative Approach to Improving System Reliability**) in statistics – deal with allowing access to data for legitimate purposes without breaking confidentiality. Techniques are being created for sound statistical analysis of distributed databases. Prototype software has been developed that anonymizes Internet transactions.

Some Final Thoughts

As of 2007, the prospects for information privacy seem distinctly mixed. On the plus side, attention to the problem, from individuals, Congress, and researchers, is high. The US National Academies issued a number of reports. There seems to be wide understanding that compromises are necessary.

Even so, it is hard not to despair. Data volume is growing exponentially. Data quality is suspect, although to many, still insufficiently so. What is considered to be data is changing. Privacy issues are difficult enough for "classical" data: subject-indexed records containing text and numbers stored on machines, but what about video images on streets (London has more than 1 million street cameras) or at public events? [5–7] Voice prints? DNA profiles? Satellite images, such as those on Google Earth?

As always, humans are at once the weakest links in the chain and the only path to dealing with the problems. Truly draconian solutions, such as radio frequency IDs implanted in children or criminals who have paid their debt to society, are possible. But so

are sensible combinations of behavior, policy, and technology that offer genuine protection.

ALAN F. KARR

Probabilistic Design

The development of probabilistic methods in engineering is of real interest for design optimization or optimization of the inspection and maintenance strategy of structures subject to reliability and availability constraints, as well as for the requalification of a structure following an incident. One of the main stumbling blocks to the development of probabilistic methods is substantiation of probabilistic models used in the studies. In fact, it is frequently necessary to estimate an extreme value (*see Solvency; Extreme Value Theory in Finance; Mathematics of Risk and Reliability: A Select History*) based on a very small sample of existing data.

Whether a deterministic or probabilistic approach is implemented, sample or database treatment must be performed. A deterministic approach involves the identification of information like minimum, maximum values, and envelope curves, while a probabilistic vision concentrates on the dispersion or variability of the value through a variation interval or fractile-type data (without prejudice to a distribution as in some deterministic or parametric analyses), or a probability distribution. A fractile or quantile of the order α is a real number, X^* , satisfying $P(X \geq X^*) = \alpha$. Treatment is compatible with the intended application, for example, determining a good distribution representation around a central value or correctly modeling behavior in a distribution tail.

Tools to describe sample dispersions are taken from the statistics; however, their effectiveness is a function of the sample size. Methods are available that may be used to adjust a probability distribution on a sample, and then verify the adequacy of this adjusted distribution in the maximum failure probability region. It is obvious that if data is lacking or scarce, these tools are difficult to use. Under such circumstances, it is entirely reasonable to refer to expert opinion to model uncertainty associated with a value, and then transcribe this information in the form of a probability distribution. This article does not describe methods available in these circumstances, and the reader is referred, for example, to the maximum entropy principle (*see Volatility Smile; Bayesian Statistics in Quantitative Risk Assessment*) [1], and other references about expert opinion and application of Bayesian methods.

The practical approach of a probabilistic analysis may be summarized by three scenarios:

Scenario 1: If a lot of experience feedback data is available, the frequentist statistic is generally used. The objectivist or frequentist interpretation associates the probability with the observed frequency of an event. In this interpretation, the confidence interval of a parameter, p , has the property that the actual value of p is within the interval with a confidence level; this confidence interval is calculated on the basis of measurements.

Scenario 2: If data is not as abundant, expert opinion (*see Expert Elicitation for Risk Assessment; Expert Judgment; Sampling and Inspection for Monitoring Threats to Homeland Security*) may be used to obtain modeling hypotheses. The Bayesian analysis is used to correct *a priori* values established on the basis of expert opinion as a function of observed events. The subjectivist (or Bayesian) interpretation interprets probability as a degree of belief in a hypothesis. In this interpretation, the confidence interval is based on a probability distribution representing the analyst's degree of confidence in the possible values of the parameter and reflecting his/her knowledge of the parameter.

Scenario 3: If no data is available, probabilistic methods may be used that are designed to reason on the basis of a model that allows the value sought to be obtained from other values (referred to as the *input parameters*). The data to be gathered thus concerns the input parameters. The quality of the probabilistic analysis is a function of the credibility of statistics concerning these input parameters and that of the model. The following may be discerned:

- a structural reliability-type approach if the value sought is a probability,
- an uncertainty propagation-type approach if a statistic around the most probable value is considered.

Scenario 1, where a large enough sample is available, i.e., the sample allows “characterization of the relevant distribution with a known and adequate precision”, begs the following questions:

1. Is the distribution type selected relevant and justifiable? Of the various statistical models available, what would be the optimal choice of distribution?

2. Would altering the distribution (all other things being equal) entail a significant difference in the results of the application?
3. How can uncertainty associated with sample representativeness be taken into consideration (sample size, quality, etc.)?

Justification is difficult for scenarios 2 and 3. For example, if the parameters of a density are adjusted as of the first moments, it must be borne in mind that a precise estimation of the symmetry coefficient requires at least 50 values while kurtosis requires 100 data points, except for very specific circumstances. Furthermore, the critical values used by tests to reject or accept a hypothesis are frequently taken from results that are asymptomatic in the sense that the sample size tends toward infinity. Thus when the sample size is small, the results of conventional tests should be handled with caution.

With respect to question 2, a study examining sensitivity to the probability distribution used provides information. There are two methods available for the sensitivity study:

- It is assumed that the distribution changes while the first moments are preserved (mean, standard deviation especially) (moment identification-type method).
- The sample is redistributed to establish the reliability data distribution parameters (through a frequential or Bayesian approach).

Another method is to take the uncertainty associated with some distribution parameters into consideration by replacing the parameters' deterministic value with a random variable. Conventional criticism concerning the statistical modeling of a database concerns are

- difficulty in interpreting experience feedback for a specific application;
- database quality, especially if few points are available;
- substantiation of the probabilistic model built.

The probabilistic modeling procedure should attempt to answer these questions. If it is not possible to define a correct probabilistic model, it is obvious that, under these circumstances, the quantitative results in absolute value are senseless in the decision

process. However, the probabilistic approach always allows results to be used relatively, notably through

- a comparison of the efficiency of various solutions from the standpoint of reliability or availability, for example;
- classification of parameters that make the biggest contribution to the uncertainty associated with the response to direct R&D work to reduce said uncertainty.

This argument concerning the quality of uncertainty probabilistic models also has repercussions on the deterministic approach.

The deterministic approach involves validation of values used and also constitutes a sophisticated problem: it is not easy to prove that a value assumed to be conservative is realistic (especially if the sample is small), or to guarantee that the value is an absolute upper- or lowerbound. Conservative values used are frequently formally associated with small or large fractiles of the orders of the values studied. However, the concept of fractile is associated with the probability distribution adjusted on the sample, and even with one of the distribution tails.

The probabilistic approach seems to be even more suitable to deal with the problem. In fact, the probabilistic model reflects the level of knowledge of variables and models, and confidence in said knowledge. By means of sensitivity studies, this approach allows the impact of the probabilistic model choice on risk to be objectively assessed. Furthermore, in the event of new information impugning probabilistic modeling, and consequently the fractiles of a variable, the Bayesian theory, that combines objective and subjective (expertise) data, allows the probabilistic model and results of the probabilistic approach to be updated stringently.

The adjustment of a probability distribution and subsequent testing of the quality of the said adjustment around the central section (or maximum failure probability region) of the distribution constitute operations that are relatively simple to implement using the available statistical software packages (SAS, SPSS, Splus, Statistica, etc.), for conventional laws, in any case. However, the interpretation and verification of results still requires the expertise of a statistician. For example, the following points

- the results of an adjustment based on a histogram is sensitive to the intervals width;

- the maximum likelihood or moment methods are not suitable for modeling a sample obtained by overlaying phenomena beyond a given limit of an observation variable;
- moment methods assume estimations of kurtosis and symmetry coefficients that are only usually specified for large bases (with at least one hundred values for kurtosis);
- most statistical tests, specifically, the most frequently used Kolmogorov–Smirnov, Anderson–Darling, and Cramer–Von Mises tests, are asymptotic tests;
- in the Bayesian approach, the distribution selected *a priori* influences the result. Furthermore, the debate concerning whether the least informative law should be used has not been concluded.

Probabilistic versus Deterministic Approach of the Design

The basis of the deterministic approach is the so-called design values for the loads and the strength parameters. Loads, for instance, are the design water level and the design-significant wave height. Using design rules according to codes and standards, it is possible to determine the shape and the height of the cross section of the flood defense.

These design rules are based on limit states of the flood defense system's elements, such as overtopping, erosion, instability, piping, and settlement.

It is assumed that the structure is safe when the margin between the design value of the load and the characteristic value of the strength is large enough for all limiting states of all elements.

The safety level of the protected area is not explicitly known when the flood defense is designed according to the deterministic approach.

The most important shortcomings of the deterministic approach are as follows:

- It is a fact that the failure probability of the system is unknown.
- The complete system is not considered as an integrated entity. An example is the design of the flood defenses of the protected area of Figure 1. With the deterministic approach, the design of the sea dike is, in both cases, exactly the same. In reality, the left area is threatened by flood from two independent causes – the sea and the river.

Figure 1 Different safety levels for the same design

Therefore, the safety level of the left area is less than the safety level of the right one.

- Another shortcoming of the deterministic approach is that the length of flood defense does not affect the design.

In the deterministic approach, the design rules are the same for all the sections, independent of the number of sections. It is, however, intuitively clear that the probability of flooding increases with the length of the flood defense (Figure 2).

- With the deterministic design methods, it is impossible to compare the strength of different types of cross sections such as dikes, dunes, and structures like sluices and pumping stations.
- Last but not least, the deterministic design approach is incompatible with other policy fields, for instance, the safety of industrial processes and the safety of transport of dangerous substances.

A fundamental difference with the deterministic approach is that the probabilistic design methods are based on an acceptable frequency or probability of flooding of the protected area.

The probabilistic approach results in a probability of failure of the whole flood defense system taking account of each individual cross section and each structure. So the probabilistic approach is an integral design method for the whole system.

Uncertainties

Uncertainties are everywhere. They surround us in everyday life. Among the numerous synonyms for “uncertainty” are unsureness, unpredictability, randomness, hazardness, indeterminacy, ambiguity, variability, irregularity, and so on. Recognition of the need to introduce the ideas of uncertainty in civil

Figure 2 Sections of a dike

engineering today reflects, in part, some of the profound changes in civil engineering over the last few decades.

Recent advancements in statistical modeling have provided engineers with an increasing power for making decisions under uncertainty. The process and information involved in the engineering problem solving are, in many cases, approximate, imprecise, and subject to change. It is generally impossible to obtain sufficient statistical data for the problem at hand, and reliance must be placed on the ability of the engineer to synthesize existing information when required. Hence, to assist the engineer in making decisions, analytical tools should be developed to effectively use the existing uncertain information.

Uncertainties in decision and risk analysis can primarily be divided into two categories: uncertainties that stem from variability in known (or observable) populations and therefore represent randomness in samples (inherent uncertainty), and uncertainties that come from basic lack of knowledge of fundamental phenomena (epistemic uncertainty (*see Protection of Infrastructure*)).

Inherent uncertainties represent randomness or variations in nature. For example, even with a long history of data, one cannot predict the maximum water level that will occur in, for instance, the coming year, at the North Sea. It is not possible to reduce inherent uncertainties.

Epistemic uncertainties are caused by lack of knowledge of all the causes and effects in physical systems, or by lack of sufficient data. For example,

it might only be possible to obtain the type of a distribution, or an exact model of a physical system, when sufficient research can be and is done. Epistemic uncertainties may change as knowledge increases.

Generally, in probabilistic design, the following five types of uncertainties are discerned (see also [2]): inherent uncertainty in time and in space, parameter uncertainty and distribution type uncertainty (together also known as *statistical uncertainty*), and finally model uncertainty. Uncertainties such as construction costs uncertainties, damage costs uncertainties, and financial uncertainties are considered to be examples of model uncertainties.

Inherent Uncertainty in Time

When determining the probability distribution of a random variable that represents the variation in time of a process (like the occurrence of a water level), there essentially is a problem of information scarcity. Records are usually too short to ensure reliable estimates of low-exceedance probability quantiles in many practical problems. The uncertainty caused by this shortage of information is the statistical uncertainty of variations in time. This uncertainty can theoretically be reduced by keeping record of the process for the coming centuries.

Stochastic processes running in time (individual wave heights, significant wave heights, water levels, discharges, etc.) are examples of the class of inherent uncertainty in time. Unlimited data will not reduce

this uncertainty. The realizations of the process in the future remain uncertain. The probability density function (PDF) or the cumulative distribution function (CDF) and the autocorrelation function describe the process.

In case of a periodic stationary process like a wave field, the autocorrelation function will have a sinusoidal form and the spectrum, as the Fourier transform of the autocorrelation function, gives an adequate description of the process. Attention should be paid to the fact that the well-known wave energy spectra such as Pierson–Moskowitz and Jonswap are not always able to represent the wave field at a site. In quite a few practical cases, swell and wind wave form a wave field together. The presence of two energy sources may be clearly reflected in the double peaked form of the wave energy spectrum.

An attractive aspect of the spectral approach is that the inherent uncertainty can be easily transferred through linear systems by means of transfer functions. By means of the linear wave theory the incoming wave spectrum can be transformed into the spectrum of wave loads on a flood defense structure. The PDF of wave loads can be derived from this wave load spectrum. Of course, it is assumed here that no wave breaking takes place in the vicinity of the structure. In case of nonstationary processes that are governed by meteorological and atmospheric cycles (significant wave height, river discharges, etc.) the PDF and the autocorrelation function are needed. Here the autocorrelation function gives an impression of the persistence of the phenomenon. The persistence of rough and calm conditions is of utmost importance in workability and serviceability analyses.

If the interest is directed to the analysis of ultimate limit states (ULSs), e.g. sliding of the structure, the autocorrelation is eliminated by selecting only independent maxima for the statistical analysis. If this selection method does not guarantee a set of homogeneous and independent observations, physical or meteorological insights may be used to homogenize the dataset. For instance, if the fetch in the north westerly (NW) direction is clearly maximal, the dataset of maximum significant wave height could be limited to NW storms. If such insight fails, one could take only the observations exceeding a certain threshold peaks over threshold (POT) (see **Extreme Values in Reliability**) into account hoping that this will lead to the desired result. In case of a clear yearly seasonal

cycle, the statistical analysis can be limited to the yearly maxima.

Special attention should be given to the joint occurrence of significant wave height H_s and spectral peak period T_p . A general description of the joint PDF of H_s and T_p is not known. A practical solution for extreme conditions considers the significant wave height and the wave steepness s_p as independent stochastic variables to describe the dependence. This is a conservative approach as extreme wave heights are more easily realized than extreme peak periods. For the practical description of daily conditions (service limit state: SLS), the independence of s_p and T_p seems sometimes a better approximation. Also the dependence of water levels and significant wave height should be explored because the depth limitation to waves can be reduced by wind setup. Here the statistical analysis should be clearly supported by physical insight. Moreover, it should not be forgotten that shoals could be eroded or accreted due to changes in current or wave regime induced by the construction of the flood defense structure.

Inherent Uncertainty in Space

When determining the probability distribution of a random variable that represents the variation in space of a process (like the fluctuation in the height of a dike), there is essentially a problem of shortage of measurements. It is usually too expensive to measure the height or width of a dike in great detail. This statistical uncertainty of variations in space can be reduced by taking more measurements [2].

Soil properties can be described as stochastic processes in space. From a number of field tests, the PDF of the soil property and the (three-dimensional) autocorrelation function can be fixed for each homogeneous soil layer. Here, the theory is more developed than the practical knowledge that is available. Numerous mathematical expressions are proposed in the literature to describe the autocorrelation. No clear preference has, however, emerged yet as to which functions describe the fluctuation pattern of the soil properties best. Moreover, the correlation length (distance where correlation becomes approximately zero) seems to be of the order of 30–100 m, while the spacing of traditional soil mechanical investigations for flood defense structures is of the order of 500 m. So it seems that the intensity of the soil

mechanical investigations has to be increased considerably if reliable estimates have to be made of the autocorrelation function.

The acquisition of more data has a different effect in case of stochastic processes in space rather than in time. As structures are immobile, there is only one single realization of the field of soil properties. Therefore, the soil properties at the location could be exactly known if sufficient soil investigations are done. Consequently, the actual soil properties are fixed after construction, although not completely known to man. The uncertainty can be described by the distribution and the autocorrelation function, but it is, in fact, a case of lack of information.

Parameter Uncertainty

This uncertainty occurs when the parameters of a distribution are determined with a limited number of data. The fewer the number of data available, the higher is the parameter uncertainty. A parameter of a distribution function is estimated from the data and is thus a random variable. The parameter uncertainty can be described by the distribution function of the parameter. In van Gelder [3], an overview of the analytical and numerical derivation of parameter uncertainties for certain probability models (exponential, Gumbel, and lognormal) is given. The bootstrap method (*see Statistics for Environmental Toxicity; Credit Migration Matrices*) is a fairly easy tool used to calculate the parameter uncertainty numerically. Bootstrapping methods are described in, for example, Efron [4]. Given a dataset $x = (x_1, x_2, \dots, x_n)$, we can generate a bootstrap sample x^* , which is a random sample of size n drawn with replacement from the dataset x . The following bootstrap algorithm can be used for estimating the parameter uncertainty:

1. Select B independent bootstrap samples $x^{*1}, x^{*2}, \dots, x^{*B}$, each consisting of n data values drawn with replacement from x .
2. Evaluate the bootstrap corresponding to each bootstrap sample;

$$\tau^*(b) = f(x^{*b}) \text{ for } b = 1, 2, \dots, B \quad (1)$$
3. Determine the parameter uncertainty by the empirical distribution function of τ^* .

Other methods to model parameter uncertainties like Bayesian methods (*see Repair, Inspection, and*

Replacement Models; Near-Miss Management: A Participative Approach to Improving System Reliability) can be applied too. Bayesian inference lays its foundations upon the idea that states of nature can be and should be treated as random variables. Before making use of data collected at the site, the engineer can express his information concerning the set of uncertain parameters Λ for a particular model $f(x|\Lambda)$, which is a PDF for the random variable x . The information about Λ can be described by a prior distribution $B(\Lambda|I)$, i.e., prior to using the observed record of the random variable x . The basis upon which these prior distributions are obtained from the initial information I are described in, for instance, van Gelder [3]. Noninformative priors can be used if we do not have any prior information available. If $p(\lambda)$ is a noninformative prior, consistency demands that $p(H) dH = p(\lambda) d\lambda$ for $H = H(\lambda)$; thus a procedure for obtaining the ignorance prior should presumably be invariant under one-to-one reparametrization. A procedure that satisfies this invariance condition is given by the Fisher matrix of the probability model:

$$I(\lambda) = -E_{x|\lambda} [M^2/M^2 \log f(x|\lambda)] \quad (2)$$

giving the so-called noninformative Jeffrey's prior $p(\lambda) = I(\lambda)^{1/2}$.

The engineer now has a set observations x of the random variable X , which he assumes comes from the probability model $f_X(x|\lambda)$. Bayes' theorem provides a simple procedure by which the prior distribution of the parameter set Λ may be updated by the dataset X to provide the posterior distribution of Λ , namely,

$$f(\Lambda|X, I) = 1(X|\Lambda)B(\Lambda|I)/K \quad (3)$$

where

$f(\Lambda|X, I)$: posterior density function for Λ , conditional upon a set of data X and information I

$1(X|\Lambda)$: sample likelihood of the observations, given the parameters

$B(\Lambda|I)$: prior density function for Λ , conditional upon the initial information I

K : is the normalizing constant ($K = E_\lambda(X|\Lambda)B(\Lambda|I)$).

The posterior density function of Λ is a function weighted by the prior density function of Λ and the data-based likelihood function in such a manner as to combine the information content of both. If future observations X_F are available, Bayes' theorem can

be used to update the PDF on Λ . In this case, the former posterior density function for Λ now becomes the prior density function, since it is prior to the new observations or the utilization of new data. The new posterior density function would also have been obtained if the two samples X and X_F had been observed sequentially as one set of data. The way in which the engineer applies his information about Λ depends on the objectives in analyzing the data.

Distribution Type Uncertainty

This type represents the uncertainty of the distribution type of the variable. It is, for example, not clear whether the changes in the water level of the North Sea is exponentially or Gumbel distributed (*see Reliability of Large Systems; Extreme Values in Reliability*), or whether it has another distribution. A choice was made to divide statistical uncertainty into parameter- and distribution-type uncertainty although it is not always possible to draw the line; in case of unknown parameters (because of lack of observations), the distribution type will be uncertain as well.

Any approach that selects a single model and then makes inference conditionally on that model ignores the uncertainty involved in the model selection, which can play a big part in the overall uncertainty. This difficulty can be avoided, in principle, if one adopts a Bayesian approach and calculates the posterior probabilities of all the competing models following directly from the Bayes factors. A composite inference can then be made that takes account of model uncertainty in a simple way with the weighted average model:

$$f(h) = A_1 f_1(h) + A_2 f_2(h) + \cdots + A_n f_n(h) \quad (4)$$

where $\sum A_i = 1$.

The approach described above gives us some sort of Bayesian discrimination (*see Risk in Credit Granting and Lending Decisions: Credit Scoring*) procedure between competing models. This area has become very popular recently. Theoretical research comes from Kass and Raftery [5], and applications can be found mainly in the biometrical sciences [6] and econometrical sciences [7]. The very few applications of Bayesian discrimination procedures in civil engineering come from Wood and Rodriguez-Iturbe [8], Pericchi and Rodriguez-Iturbe [9, 10], and Perreault *et al.* [11].

Model Uncertainty

Many engineering models describing natural phenomena like wind and waves are imperfect. They can be imperfect because the physical phenomena are not known (for example, when regression models without the underlying physics are used), or they can be imperfect because some variables of lesser importance are omitted in the engineering model for reasons of efficiency.

Suppose that the true state of nature is X . Prediction of X may be modeled by X^* . As X^* is a model of the real world, imperfections may be expected; the resulting predictions will therefore contain errors and a correction N may be applied. Consequently, the true state of nature may be represented by Ang [12]:

$$X = NX^* \quad (5)$$

If the state of nature is random, the model X^* naturally is also a random variable, for which a normal distribution will be assumed. The inherent variability is described by the coefficient of variation (CV) of X^* , given by $\sigma(X^*)/\mu(X^*)$. The necessary correction N may also be considered a random variable, whose mean value $\mu(N)$ represents the mean correction for systematic error in the predicted mean value, whereas the CV of N , given by $\sigma(N)/\mu(N)$, represents the random error in the predicted mean value.

It is reasonable to assume that N and X^* are statistically independent. Therefore, we can write the mean value of X as

$$\mu(X) = \mu(N)\mu(X^*) \quad (6)$$

The total uncertainty in the prediction of X becomes

$$CV(X) = \sqrt{(CV^2(N) + CV^2(X^*) + CV^2(N)CV^2(X^*))} \quad (7)$$

In van Gelder [3], an example of model uncertainty is presented by fitting physical models to wave impact experiments.

We can ask ourselves if there is a relationship between model and parameter uncertainty. The answer is "No". Consider a model for predicting the weight of an individual as a function of his height. This might be a simple linear correlation of the form $W = aH + b$. The parameters a and b may be found from a least squares fit to some sample data. There

will be *parameter* uncertainty to a and b due to the sample being just that – a sample, not the whole population. Separately, there will be *model* uncertainty due to the scatter of individual weights either side of the correlation line.

Thus parameter uncertainty is a function of how well the parameters provide a fit to the population data, given that they would have been fitted using only a sample from that population, and that sample may or may not be wholly representative of the population. Model uncertainty is a measure of the scatter of individual points either side of the model once it has been fitted. Even if the fitting had been performed using the whole population, there would still be residual errors for each point since the model is unlikely to be exact.

Parameter uncertainty can be reduced by increasing the amount of data against which the model fit is performed. Model uncertainty can be reduced by adopting a more elaborate model (e.g., quadratic fit instead of linear). There is, however, no relationship between the two.

Uncertainties Related to the Construction

To optimize the design of a hydraulic structure, the total lifetime costs – an economic cost criterion – can be used. The input for the cost function consists of uncertain estimates of the construction cost and the uncertain cost in case of failure.

The construction costs consist of a part that is a function of the structure geometry (variable costs) and a part that can only be allocated to the project as a whole (fixed costs). For a vertical breakwater, for instance, the variable costs can be assumed to be proportional to the volumes of concrete and filling sand in the cross section of the breakwater.

The costs in case of ULS (see **Structural Reliability**) failure consist of replacement of (parts of) the structure and thus depend on the structure dimensions. The costs in case of SLS failure are determined by the costs of downtime and are thus independent of the structure geometry.

The total risk over the lifetime of the structure is given by the sum of all yearly risks, corrected for interest, inflation, and economical growth. This procedure is known as *capitalization*. The growth rate expresses that, in general, the value of all goods and equipment behind the hydraulic structure will increase during the lifetime of the structure.

Several cost components can be allocated to the building project as a whole. Examples of these cost components are

- cost of the feasibility study;
- cost of the design of the flood protection structure;
- site investigations, like penetration tests, borings and surveying;
- administration.

In principle, there are two ways in which a structure can fail. Either the structure collapses under survival conditions after which there will be more wave penetration in the protected area or the structure is too low and allows too much wave generation in the protected area due to overtopping waves. In both cases, possibly harbor operations have to be stopped, resulting in (uncertain amount of) damage (downtime costs).

If a structure fails to protect the area of interest against wave action, possibly the operations in this area will have to be stopped. The damage costs that are caused by this interruption of harbor operations are called *downtime costs*. The exact amount of downtime costs is very difficult to determine and therefore contain a lot of uncertainty. The downtime costs for one single ship can be found in literature, but the total damage in case of downtime does not depend solely on the downtime costs of ships. The size of the harbor and the type of cargo are also important variables in this type of damage. Furthermore, the availability of an alternative harbor is very important. If there is an alternative, ships will use this harbor. In that case, the damaged harbor will lose income because less ships make use of the harbor and possibly because of claims of shipping companies. On a macroeconomic scale, however, there is possibly minor damage since the goods are still coming in by way of the alternative harbor. This also shows that the availability of infrastructure in the area influences the damage in case of downtime. If an alternative harbor is not available, the economic damage may be felt beyond the port itself.

The location of the structure in relation to the harbor also influences the damage costs. If the structure protects the entrance channel, the harbor cannot be reached during severe storms, thus causing waiting times. These waiting times have the order of magnitude of hours to a few days. If the structure protects the harbor basin or a terminal, damage to the structure can cause considerable amounts of extra

downtime owing to the fact that the structure only partly fulfills its task over a longer period of time.

If the load on a structure component exceeds the admissible load, the component collapses. Several scenarios are now possible:

- The component is not essential to the functionality of the structure. Repair is not carried out and there is no damage in monetary terms. This is the case if, for instance, an armor block is displaced in the rubble foundation. It should be noted that this kind of damage can cause failure if a lot of armor blocks are displaced (preceding failure mode).
- The component is essential to the functionality of the structure. The stability of the structure is, however, not threatened. This is the case if, for instance, the crown wall of a caisson collapses. The result is a reduction of the crest height of the structure, which could threaten the functionality of the structure. Therefore, repair has to be carried out and there is some damage in monetary terms.
- The structure has become unstable during storm conditions. There is considerable damage to the structure, resulting in necessary replacement of (parts of) the structure. The damage in monetary terms is possibly even higher than the initial investment in the structure.

When optimizing a structural design, an estimate of the damage is needed. In the case of a structure component, this could be the cost of rebuilding. If large parts of the caissons have collapsed, the area would have to be cleared before rebuilding the structure. In that case, the damage would be higher than in the case of rebuilding alone. Furthermore, collapse, in general, leads to downtime cost which further increases the damage.

Reduction of Uncertainty

Inherent uncertainties represent randomness or variations in nature. Inherent uncertainties cannot be reduced. Epistemic uncertainties, on the other hand, are caused by lack of knowledge. Epistemic uncertainties may change as knowledge increases. In general, there are three ways to increase knowledge:

- gathering data
- research
- expert judgment.

Data can be gathered by taking measurements or by keeping record of a process in time. Research can, for instance, be undertaken with respect to the physical model of a phenomenon or into the better use of existing data. By using expert opinions, it is possible to acquire the probability distributions of variables that are too expensive or practically impossible to measure.

The goal of all this, obviously, is to reduce the uncertainty in the model. Nevertheless, it is also thinkable that uncertainty will increase. Research might show that an originally flawless model actually contains a lot of uncertainties. Or after taking some measurements, the variations of the dike height can be a lot larger. It is also thinkable that the average value of the variable will change because of the research that has been done.

The consequence is that the calculated probability of failure will be influenced by future research. To guarantee a stable and convincing flood defense policy after the transition, it is important to understand the extent of this effect.

Probabilistic Approach of the Design

The accepted probability of flooding is not the same for every polder or floodplain. It depends on the nature of the protected area, the expected loss in case of failure, and the safety standards of the country. For instance, for a protected area with a dense population or an important industrial development, a smaller probability of flooding is allowed than for an area of lesser importance.

For this reason accepted risk is a better measure than an accepted failure probability, because risk is a function of the probability and the consequences of flooding.

The most general definition of risk is the product of the probability and a power of consequences:

$$Risk = (probability) \cdot (consequence)^n \quad (8)$$

In many cases, such as economic analyses, the power n is equal to 1.

Figure 3 shows the elements of the probabilistic approach. First of all the flood defense system has to be described as a configuration of elements such as dike sections, sluices, and other structures. Then an inventory of all the possible hazards and failure modes must be made. This step is one of the most

Figure 3 Probabilistic approach of the design

important of the analysis because missing a failure mode can seriously influence the safety of the design.

The next step can be the quantifying of the consequences of failure. Here, it is necessary to analyze the consequence of the failure for all possible ways of failure. Sometimes, the consequences of failure of an element of the system are different for each element.

The failure probability and the probability of the consequences form the probability part of the risk. When the risk is calculated, the design can be evaluated. For this, criteria must be available such as a maximum acceptable probability of a number of casualties or the demand of minimizing the total costs

including the risk. For determining the acceptable risk, we need a frame of reference. This frame of reference can be the national safety level aggregating all the activities in the country.

After the evaluation of the risk, one can decide to adjust the design or to accept it with the remaining risk.

System Analysis

Every risk analysis, which is the core of the probabilistic design, starts with a system analysis. There are several techniques to analyze a system, but in this

Figure 4 Input–output model

Figure 5 Fault tree

case we restrict ourselves to the input–output model (Figure 4) and the fault tree analysis.

With the input–output model the elements of the system are schematized as fuses in an electrical scheme. When an element fails, the connection is broken and there will be no current through the element. So in this case, there will be no output.

The fault tree arranges all the events in such a way that their occurrence leads to failure of the system. Figure 5 is an example of a fault tree. A fault tree (*see Canonical Modeling; Systems Reliability; Imprecise Reliability; Reliability Data*)

consists of basic events ($E1 \dots E9$), combined events ($E10 \dots E12$), a top event (failure), and gates (and, or). A gate is the relation of the events beneath the gate that lead to the event above it.

Simple Systems

The most simple systems are the parallel and the series systems (Figure 6). A parallel system that consists of two elements functions as long as one of the elements functions.

When a system fails if only one element fails, it is called a *series system*.

What can we say about the strength of these systems? Let us start with the series system. For instance, in the case of a chain which is loaded by a tensile force (Figure 7) the chain is as strong as the weakest link.

A parallel system that consists of two ductile steel columns in a frame is as strong as the sum of the strengths of the two columns (see Figure 8).

When the elements and their failure modes are analyzed, it is possible to make a fault tree. The fault tree gives the logical sequence of all the possible events that lead to failure of the system.

Take, for instance, the fault tree of a simple parallel system. The basic events are the failure of the single elements, and the failure of the system is called the *top event*. The system fails only when all single elements fail. So the gate between the basic events and the top event is a so-called and-gate (see Figure 9).

A series system of two elements fails if only one of the elements fails as depicted by the so-called or-gate between the basic events and the top event (see Figure 10).

When there are more failure modes possible for the failure of an element, then the failure modes are the basic events and the failure of an element is a so-called composite event.

Figure 6 Parallel and series systems

Figure 7 A chain as a series system

Figure 8 A frame as a parallel system

Figure 9 Fault tree of a parallel system

Figure 11 is an example (after [13]) of a parallel system of elements in which the system elements are in turn series systems of the possible failure modes.

Example: Risk Analysis of a polder

An overview of the flood defense system of a polder is given in Figure 12. Failure of the subsystems (dike, dune sluice, and levee) of the system leads to flooding of the polder.

The subsystems all consist of elements. The dikes can, for instance, be divided into sections. This is also shown in Figure 12. Failure of any of the elements

Figure 10 Fault tree of a series system

Figure 11 Elements of a parallel system as series systems of failure modes

of the subsystem “dike 1” leads to flooding of the polder.

For all the elements of the flood defense, all the possible failure modes can be the cause of failure. A failure mode is a mechanism that leads to failure. The most important failure modes for a dike section are given in Figure 13. The place of the failure modes in the system is demonstrated by a fault tree analysis in Figures 14 and 15.

An advantage of the probabilistic approach above the deterministic approach is illustrated in Figure 15, where human failure to close the sluice is included in the analysis.

The conclusion of this analysis is that any failure mechanism of any element of any subsystem of the flood defense system can lead to inundation of the polder. The system is, therefore, a series system.

Figure 12 Flood defense system and its elements presented in a fault tree

Failure Probability of a System

This article gives an introduction of the determination of the failure probability of a system for which the failure probabilities of the elements are known.

Two fault trees given in Figure 16 – one for a parallel system and one for a series system – both consisting of two elements.

Event A is the event that element 1 fails and B is the event that element 2 fails.

The parallel system fails if both the elements fail. The failure probability is the probability of A and B . The series system fails if at least one of the elements fail. So the failure probability is the probability of A or B (see Figure 17).

The probability of A and B is equal to the product of the probability of A and the probability of B given A . The probability of A or B is equal to the sum of the probability of A and the probability of B minus the probability of A and B .

In practice, the evaluation of the probability of B given A is rather difficult because the relation between A and B is not always clear. If A and B are independent of each other, the probability of B given A is equal to the probability of B without A .

In this case, the probability of A and B is equal to the product of the probability of A and the probability of B :

$$P(B|A) = P(B) \implies P(A \cap B) = P(A)P(B) \quad (9)$$

If event A excludes B , then the probability B and A is zero:

$$P(B|A) = 0 \implies P(A \cap B) = 0 \quad (10)$$

If A includes B , then the probability of B given A is 1 and so the probability of A and B is equal to the probability of A

$$P(B|A) = 1 \implies P(A \cap B) = P(A) \quad (11)$$

In the same way, it is possible to determine the probability of A or B . If A and B are independent of each other the probability of A or B is

$$P(A \cup B) = P(A) + P(B) - P(A)P(B) \quad (12)$$

If event A excludes B , then the probability B and A is zero so the probability of A or B is

$$P(A \cup B) = P(A) + P(B) \quad (13)$$

Figure 13 Failure modes of a dike [Reproduced from [13] with permission from Springer, © 1986.]

If A includes B , then the probability of B given A is 1 and so the probability of A and B is equal to the probability of A and the probability of A or B is

$$P(A \cup B) = P(A) + P(B) - P(A) \quad (14)$$

In many cases, the events A and B are each described by a stochastic variables Z_1 and Z_2 , respectively. Event A occurs when $Z_1 < 0$ and event B occurs when $Z_2 < 0$. This is further explained in the next section on probability estimation of an element. In many cases, as for instance, when there is a linear relation between Z_1 and Z_2 , the dependency of the events A and B can be described by the correlation coefficient. This is defined by

$$\rho = \frac{\text{Cov}(Z_1 Z_2)}{\sigma_{Z_1} \sigma_{Z_2}} \quad (15)$$

where

σ_{Z_1} : standard deviation of Z_1

σ_{Z_2} : standard deviation of Z_2

$\text{Cov}(Z_1 Z_2)$: covariance of Z_1 and Z_2

: $E((Z_1 - \mu_{Z_1})(Z_2 - \mu_{Z_2}))$

: expected value of $(Z_1 - \mu_{Z_1})(Z_2 - \mu_{Z_2})$

$f_{Z_1}(\xi_1)$: probability density function of Z_1

In the graph of Figure 18, the probability of A or B is plotted against the correlation coefficient. The probability of B is the lower limit of the failure probability and the sum of the probability of A and the probability of B is the upper limit of the failure probability.

Figure 14 A dike section as a series system of failure modes

Figure 15 The sluice as a series system of failure modes

Figure 16 Fault trees for parallel and series systems

It can be seen that as long as the correlation coefficient is less than 90%, the failure probability is close to the upper limit.

In case of a series system with a large number of elements, the lower and upper bounds are as follows

- the maximum probability of the failure of a single element;
- and the sum of the failure probabilities of all the elements.

$$\max(P(i)) \leq P_f \leq \sum_{i=1}^n P(i) \quad (16)$$

Figure 18 Probability of A or B, given ρ

Ditlevsen has narrowed these boundaries to get a better estimation of the failure probability.

$$P(1) + \sum_{i=2}^n \max \left(P(i) - \sum_{j=1}^{i-1} P(i \cap j) \right) \leq P_f$$

$$P_f \leq \sum_{i=1}^n P(i) - \sum_{i=2}^n \max_{j < i} (P(i \cap j)) \quad (17)$$

Let us now look at a series system that consists of two elements, each having two failure modes.

If the probabilities of the potential failure modes are known, it is possible to determine the upper limit of the failure probabilities of the element as the sum of the probabilities of the two different failure modes. The upper limit of the probability of failure of the system can be determined as the sum of the upper

limits of the failure probability of the two elements. So the upper limit of the failure probability is the sum of the probability of all the failure modes.

The scheme in Figure 19 for computation of the upper limit of the failure probability can also be used top down. For instance, if the allowable failure probability of the system is known, the scheme can be used to distribute this probability among the failure modes. In this way, we get a boundary condition for each failure mode that can be applied for the design.

Estimation of the Probability of a Failure Mode of an Element

After analyzing the failure probability of the system as a function of the probabilities of the failure modes, we need to know the probabilities of failure modes to estimate the failure probability. These probabilities can be determined by analyzing historical failure data or by probabilistic calculation of the limit states.

For most cases, there is not enough specific failure data available, so we have to determine the failure probabilities by computation.

The probabilistic computation uses the reliability function and the PDF of the variables as the base for the determination of the failure probability. A reliability function is a function of the strength and the load for a particular failure mode. In general, the formulation of the reliability function is given by $Z = R - S$ where R is the strength and S is the load. The failure mode will not occur as long as the

Figure 19 Probability of failure of a series system

Figure 20 Reliability function

reliability function is positive. The graph of Figure 20 shows the reliability function. The line $Z = 0$ is a limit state. This line represents all the combinations of values of the strength and the loading for which the failure mode will just not occur. So it is a boundary between functioning and failure.

In the reliability function, the strength and load variables are assumed to be stochastic variables.

A stochastic variable is a variable that is defined by a probability distribution and a probability density function.

The probability distribution $F(x)$ returns the probability that the variable is less than x (as shown in Figure 21).

The PDF is the first derivative of the probability distribution.

If the distribution and the density of all the strength and load variables are known, it is possible to estimate the probability that the load has a value x and that the strength has a value less than x (see Figure 22).

$$\left. \begin{aligned} P(S = x) &= f_S(x) dx \\ P(R \leq x) &= F_R(x) \end{aligned} \right\} \implies P(S = x \cap R \leq x) = f_S(x) F_R(x) dx \quad (18)$$

The failure probability is the probability that $S = x$ and $R < x$ for every value of x . So we have to

Figure 21 Probability distribution and probability density

Figure 22 Components of the failure probability

Figure 23 Joint probability density function

compute the sum of the probabilities for all possible values of x :

$$P_f = \int_{-\infty}^{\infty} f_S(x) F_R(x) dx \quad (19)$$

This method can be applied when the strength and the load are independent of each other.

Figure 23 gives the joint probability density of the strength and the load for a certain failure mode in which the strength and the load are not independent.

The strength is plotted on the horizontal axis and the load is plotted on the vertical axis.

The contours give the combinations of the strength and the load with the same probability density. In the area ($Z < 0$) the value of the reliability function is less than zero and the element will fail.

The failure probability can be determined by summation of the probability density of all the combinations of strength and load in this area.

$$P_f = \iint_{Z < 0} f_{RS}(r, s) dr ds \quad (20)$$

In a real case, the strength and the load in the reliability function are nearly always functions of multiple variables. For instance, the load can consist of the water level and the significant wave height. In this case, the failure probability is less simple to evaluate. Nevertheless, with numerical methods like numerical integration and Monte Carlo simulation (see **Risk Measures and Economic Capital for**

(Re)insurers; Structured Products and Hybrid Securities; Reliability Optimization; Uncertainty Analysis and Dependence Modeling), it is possible to solve the integral

$$P_f = \iint_{Z < 0} \dots \iint f_{r_1, r_2, \dots, r_n, s_1, s_2, \dots, s_m} \times (r_1, r_2, \dots, r_n, s_1, s_2, \dots, s_m) \times dr_1 dr_2 \dots r_n ds_1 ds_2 \dots ds_m \quad (21)$$

These methods that take into account the real distribution of the variables are called *level III probabilistic methods*. In the Monte Carlo simulation method, a large sample of values of the basic variables is generated and the number of failures is counted. The number of failures equals

$$N_f = \sum_{j=1}^N 1(g(\mathbf{x}_j)) \quad (22)$$

where N is the total number of simulations. The probability of failure can be estimated by

$$P_f \approx \frac{N_f}{N} \quad (23)$$

The CV of the failure probability can be estimated by

$$V_{P_f} \approx \frac{1}{\sqrt{P_f N}} \quad (24)$$

where P_f denotes the estimated failure probability.

The accuracy of the method depends on the number of simulations. The relative error made in the simulation can be written as

$$\varepsilon = \frac{\frac{N_f}{N} - P_f}{P_f} \quad (25)$$

The expected value of the error is zero. The standard deviation is given as

$$\sigma_\varepsilon = \sqrt{\frac{1 - P_f}{N P_f}} \quad (26)$$

For a large number of simulations, the error is normally distributed. Therefore, the probability that the relative error is smaller than a certain value E can be written as

$$P(\varepsilon < E) = \Phi\left(\frac{E}{\sigma_\varepsilon}\right) \quad (27)$$

$$N > \frac{k^2}{E^2} \left(\frac{1}{P_f} - 1 \right) \quad (28)$$

The probability of the relative error E being smaller than $k\sigma_\varepsilon$ now equals $\Phi(k)$. For desired values of k and E , the required number of simulations is determined as follows: For relative error of $E = 0.1$ lying within the 95% confidence interval ($k = 1.96$),

$$N > 400 \left(\frac{1}{P_f} - 1 \right) \quad (29)$$

The equation shows that the required number of simulations, and thus the calculation time, depend on the probability of failure to be calculated. Most structures in coastal and river engineering possess a relatively high probability of failure (i.e., a relatively low reliability) compared to structural elements/systems, resulting in reasonable calculation times for Monte Carlo simulation. The calculation time is independent of the number of basic variables and therefore Monte Carlo simulation should be favored over the Riemann method in case of a large number of basic variables (typically more than five). Furthermore, the Monte Carlo method is very robust, meaning that it is able to handle discontinuous failure spaces and reliability calculations in which more than one design point is involved (see below).

The problem of long calculation times can be partly overcome by applying importance sampling. This is not elaborated upon here. Reference is made to [14, 15].

If the reliability function (Z) is a sum of a number of normal distributed variables, then Z is also a normal distributed variable. The mean value and the standard deviation can easily be computed with these equations:

$$Z = \sum_{i=1}^n a_i x_i, \mu_Z = \sum_{i=1}^n a_i \mu_{x_i},$$

$$\sigma_Z = \sqrt{\sum_{i=1}^n (a_i \sigma_{x_i})^2} \quad (30)$$

This is the base of the level II probabilistic calculation. The level II methods approximate the distributions of the variables with normal distributions and they estimate the reliability function with a linear first order Taylor polynomial, so that the Z function is normal distributed.

If the distribution of the Z function is normal and the mean value and the standard deviation are known, it is rather easy to determine the failure probability (as shown in Figure 24).

By computing β as μ divided by σ it is possible to use the standard normal distribution to estimate the failure probability.

Tables of the standard normal distribution are available in the handbooks for statistics.

Nonlinear Z Function

A nonlinear Z function (see **Comonotonicity; Risk Classification/Life; Optimal Stopping and Dynamic Programming**) can be estimated with a

Figure 24 Probability density of the Z function

Taylor polynomial

$$Z(\vec{x}) \approx Z(\vec{x}^*) + \sum_{i=1}^n \frac{\partial Z}{\partial x_i} \cdot (x_i - x_i^*) \quad (31)$$

The function depends on the point where it is linearized. The mean value and the standard deviation of the linear Z function can be determined easily. If the reliability function is estimated by a linear Z function at the point where all the variables have their mean values ($x_i^* = \mu_{x_i}$), we call it a *mean value approach*.

The so-called design point approach estimates the reliability function by a linear function at a point on $Z = 0$ where the joint PDF has a maximum. Finding the design point is a maximization problem. For this problem, there are several numerical solutions, which are not discussed here.

Nonnormally Distributed Basic Variables

If the basic variables of the Z function are not normally distributed the Z function will be unknown and probably nonnormally distributed. To cope with this problem, the nonnormally distributed basic variables in the Z function can be replaced by a normally distributed variable. In the design point, the adapted normal distribution must have the same value as the real distribution. Because the normal distribution has two parameters (μ and σ), one condition is not enough to find the right normal distribution. Therefore, the value of the adapted normal PDF must also have the same value as the real PDF (see Figure 25).

The two conditions give a set of two equations with two unknowns, which can be solved:

$$\left. \begin{aligned} F_N(x^*) &= F_x(x^*) \\ f_N(x^*) &= f_x(x^*) \end{aligned} \right\} \implies \mu_N, \sigma_N \quad (32)$$

Figure 25 Adapted normal distribution

This method is known as the *approximate full distribution approach* (AFDA).

Acceptable Risk

A philosophy for acceptable risk (*see Actuary; Human Reliability Assessment; Multiattribute Modeling*) that takes into account the cost/benefit and the voluntariness aspect was developed by the Technical Advisory Committee for Water Retaining Structures [16]. The safety standard consists of a flexible evaluation of the individual and the societal acceptable risk but adds to these an economic approach taking the material damage into account. The latter provides the link with the safety philosophy of the Dutch dikes that was developed after the 1953 flood in the southwest of the Netherlands.

Personally Acceptable Level of Risk

The smallest component of the socially accepted level of risk is the personal assessment of risks by the individual. As an attempt to model this appraisal procedure quantitatively is not feasible, it is proposed to look with the insight gained to the preferences revealed in the accident statistics.

The actual personal risk levels inherent to various activities show statistical stability over the years and are approximately equal for the western countries, indicating a consistent pattern of preferences. The probability of losing one's life in normal daily activities such as driving a car or working in a factory appears to be 1 or 2 orders of magnitude lower than the overall probability of dying. Only a purely voluntary activity such as mountaineering entails a higher risk (Figure 26). This observation of public tolerance of 1000 times greater risks from voluntary than from involuntary activities with the same benefit was already made in the early 1970s.

In view of the consistency and the stability of the death risks presented, apart from a slightly downward trend due to technical progress, it would appear permissible to deduce there from a guideline for decisions with regard to the personally acceptable probability of failure

$$P_{fi} = \frac{\beta_i 10^{-4}}{P_{d|fi}} \quad (33)$$

Figure 26 Personal risks in western countries, deduced from the statistics of causes of death and the number of participants per activity

where $P_{d|fi}$ denotes the probability of being killed in the event of an accident.

In this expression, the policy factor, β_i varies with the degree of voluntariness with which an activity is undertaken and with the benefit perceived. It ranges from 100 in the case of complete freedom of choice like mountaineering, to 0.01 in case of an imposed risk without any perceived direct benefit. This last case includes the individual risk criterion proposed by VROM [17], for the siting of a hazardous installation near a housing area without any direct benefit to the inhabitants.

Socially Acceptable Level of Risk

The basis of the framework with respect to societal risk is an evaluation of risks due to a certain activity on a national level. The risk evaluation on a national level has to be translated to local installations or activities to support a systematic appraisal by the local authorities.

If a risk criterion is defined on a local level (such as in [18]), the height of the national risk criterion is determined by the number of locations, where the activity takes place, and the type of PDF of the consequences of an accident. The resulting national norm has to be evaluated, as it was not intentionally formulated. It seems preferable to start with a risk criterion on a national level and to evaluate the acceptable local risk level in view of

the actual number of installations, the cost/benefit aspects of the activity and the general progress in safety in an iterative process with, say, a 10-year cycle (Figure 27).

Nationally Acceptable Level of Risk

The determination of the socially acceptable level of risk starts from the proposition that the result of a social process of risk appraisal is reflected in the accident statistics. It seeks to derive a standard from these revealed preferences. Using the circle of acquaintances as an instrument of observation, the very low probabilities of a fatal accident, which appear socially acceptable, are perceptible. The recurrence time is within the order of magnitude of a human life span.

In seeking to establish a norm for the acceptable level of risk for engineering structures it is more realistic to base oneself on the probability of a death due to a nonvoluntary activity in the factory, on board a ship, at sea, etc. which is approximately equal to: $1.4 \times 10^{-3} \text{ year}^{-1}$.

If this observation-based frequency is adopted as the norm for assessing the safety of activity i , then after rearranging the expression, and adopting a rather arbitrary distribution over some 20 categories of activities, each claiming an equal number of lives per year, the following norm is obtained for an activity i

Figure 27 Framework for risk management

with N_{pi} participants in the Netherlands:

$$P_{fi} N_{pi} P_{d|fi} < \beta_i \times 100 \quad (34)$$

This norm should be interpreted in the sense that an activity is permissible as long as it is expected to claim fewer than $\beta_i \times 100$ deaths per year (in general: $\beta \times 7.10^{-6} \times$ national population size). The formula does not account for the standard deviation, which will certainly influence acceptance by a risk-averse community.

Risk aversion can be represented mathematically by increasing the mathematical expectation of the total number of deaths, $E(N_{di})$ by the desired multiple k of the standard deviation before the situation is tested against the norm:

$$E(N_{di}) + k \sigma(N_{di}) < \beta_i \times 100 \quad (35)$$

where

k : risk aversion index.

To determine the mathematical expectation and the standard deviation of the total number of deaths occurring annually in the context of activity i , it

is necessary to take into account the number of independent places N_A where the activity under consideration is carried out.

The model is tested for several activities in Vrijling *et al.* [19]. The agreement between the norm derived in this study for reasonable values of N_A and $0.01 < \beta_i < 100$ and the risk accepted in practice in the Netherlands seems to support the model.

Locally Acceptable Level of Risk

The translation of the nationally acceptable level of risk to a risk criterion for one single installation or location where an activity takes place depends on the distribution type of the number of casualties for accidents of the activity under consideration as shown above. To relate the new framework to the present one, it is assumed that on a local level the societal risk criterion is of the type proposed by VROM [17]:

$$1 - F_{N_{dij}}(x) < \frac{C_i}{x^2} \quad \text{for all } x \geq 10 \quad (36)$$

Assuming a Bernoulli distribution of the number of casualties, in the national criterion equation, and

taking account of N_{Ai} independent locations, gives the value of C_i

$$C_i = \left[\frac{-k\sqrt{N_{Ai}} + \sqrt{k^2 N_{Ai} + 4 \frac{N_{Ai}}{N} \beta_i \times 100}}{2 \frac{N_{Ai}}{N}} \right]^2 \quad (37)$$

If the expected value of the number of deaths is much smaller than its standard deviation, which is often true for calamities, the previous result reduces to

$$C_i = \left[\frac{\beta_i \times 100}{k\sqrt{N_{Ai}}} \right]^2 \quad (38)$$

Similar results are obtained for the exponential distribution.

The national societal acceptable risk criterion leads to a local acceptable risk criterion of the VROM type [17], which is inversely proportional to the number of independent places N_A and the square of the policy factor β_i :

$$1 - F_{N_{dij}}(x) \leq \frac{C_i}{x^2} \quad \text{for all } x \geq 100$$

$$\text{where } C_i = \left[\frac{\beta_i \times 100}{k\sqrt{N_{Ai}}} \right]^2 \quad (39)$$

The VROM rule is a special case of this general framework for acceptable risk: with $C_i = 10^{-3}$, $N_A = 1000$ (the approximate number of chemical installations), and $k = 3$, it follows that $\beta = 0.03$ which, according to Figure 26 is not unreasonable for an involuntarily imposed risk.

Economically Optimal Level of Risk

The problem of the acceptable level of risk can also be formulated as an economic decision problem. The expenditure I for a safer system is equated with the gain made by the decreasing present value of the risk (Figure 28).

The optimal level of safety indicated by P_{topt} corresponds to the point of minimal cost.

$$\min(Q) = \min(I(P_f) + PV(P_f S)) \quad (40)$$

where

Q : total cost

Figure 28 The economically optimal probability of failure of a structure

$I(P_f)$: investment to obtain a safety level corresponding P_f

PV : present value operator

S : total damage in case of failure.

If despite ethical objections, the value of a human life is rated at s , the amount of damage is increased to

$$P_{d|fi} N_{pi} s + S \quad (41)$$

where

N_{pi} : number of participants in activity I .

This extension makes the optimal failure probability a decreasing function of the expected number of deaths.

The valuation of human life is chosen as the present value of the net national product per inhabitant. The advantage of taking the possible loss of lives into account in economic terms is that the safety measures are affordable in the context of the national income. Risk aversion may also be included in the economic approach as shown by van Gelder and Vrijling [20].

Probabilistic Risk Assessment

Definition

Probabilistic risk assessment (PRA) (*see* **Environmental Health Risk Assessment**) is a systematic procedure for investigating how complex systems are built and operated. The PRAs model how human, software, and hardware elements of the system interact with each other. Also, they assess the most significant contributors to the risks of the system and determine the value of the risk. A formal definition proposed by Kaplan and Garrick [1] provides a simple and useful description of the elements of risk assessment that involves addressing three basic questions:

1. What can go wrong that could lead to exposure of hazards?
2. How likely is this to happen?
3. If it happens, what consequences are expected?

The PRA procedure involves quantitative application of the above triplets, in which probabilities (or frequencies) of scenarios of events leading to exposure of hazards are estimated and the corresponding magnitude of health, safety, environmental, and economic consequences for each scenario are predicted. The risk value (i.e., expected loss) of each scenario is often measured as the product of the scenario frequency and its consequences. The main result of the PRA is not the actual value of the risk computed (the so-called bottom-line number); rather it is the determination of the system elements that substantially contribute to the risks of that system, uncertainties associated with such estimates, and effectiveness of various risk reduction strategies available. In the remainder of this article, major steps in conducting a PRA are discussed.

Steps in Conducting a Probabilistic Risk Assessment

The following subsections provide a discussion of the essential components of PRA as well as the steps that must be performed in a PRA analysis.

The NASA PRA Guide [2] describes the components of the PRA as shown in Figure 1. In the following sections, each component of PRA is discussed in more details.

Objectives and Methodology

Preparing for a PRA begins with a review of the objectives of the analysis. Among many objectives that are possible, the most common ones include design improvement, risk acceptability, decision support, regulatory and oversight support, and operations and life management. Once the objectives are clarified, an inventory of possible techniques for the desired analyses should be developed. This step, in essence, provides a road map for the analysis. See Modarres [3] and Kumamoto and Henley [4] for the inventory of methodological approaches to PRA.

Familiarization and Information Assembly

A general knowledge of the physical layout of the overall system (e.g., facility, design, process, aircraft, or spacecraft), administrative controls, maintenance and test procedures, as well as barriers and subsystems, whose job is to protect, prevent, or mitigate hazard exposure conditions, is necessary to begin the PRA. A detailed inspection of the overall system must be performed in the areas expected to be of interest and importance to the analysis. The following items should be performed in this step:

1. Major critical barriers, structures, emergency safety systems, and human interventions should be identified.
2. Physical interactions among all major subsystems (or parts of the system) should be identified and explicitly described. The result should be summarized in a dependency matrix (*see* **Default Correlation**).
3. Past major failures and abnormal events that have been observed in the facility should be noted and studied. Such information would help ensure inclusion of important applicable scenarios.
4. Consistent documentation is critical to ensure the quality of the PRA. Therefore, a good filing system must be created at the outset and maintained throughout the study.

Figure 1 Components of the overall PRA process [Reproduced from [2]. National Aeronautics and Space Administration, 2002.]

Identification of Initiating Events

This task involves identifying those events (abnormal events or conditions) that could, if not correctly and timely responded to, result in hazard exposure (*see History and Examples of Environmental Justice; Combining Information; Bonus–Malus Systems; Longevity Risk and Life Annuities*). The first step involves identifying sources of hazard and barriers around these hazards. The next step involves identifying events that can lead to a direct threat to the integrity of the barriers.

During the normal operation mode of a system, loss of certain functions or subsystems will cause the process to enter an off-normal (transient) state transition. Once in this transition, there are two possibilities. First, the state of the system could be such that no other function is required to maintain the process in a safe condition (safe refers to a mode where the chance of exposing hazards beyond the system boundaries is negligible). The second possibility is a state wherein other functions (and thus systems) are required to prevent exposing hazards beyond the system boundaries. For this second possibility, the loss of the function or the system is considered an initiating event. Since such an event is related to the normally operating equipment, it is called an *operational initiating event*.

One method for determining the operational initiating events begins with first drawing a functional block diagram (*see Failure Modes and Effects*

Analysis) of the system. From the functional block diagram, a hierarchical relationship is produced, with the process objective being the successful completion of the desired system. Each function can then be decomposed into its subsystems and components and combined in a logical manner to represent operations needed for the success of that function.

An alternative to the use of functional hierarchy for identifying initiating events is the use of failure mode and event analysis (FMEA) (*see Human Reliability Assessment; Reliability Integrated Engineering Using Physics of Failure*) (*see Stamatis [5]*). The difference between these two methods is noticeable, namely, the functional hierarchies are deductively and systematically constructed, whereas FMEA is an inductive and experiential technique. In both of the above methods, one can always supplement the set of initiating events with generic initiating events (if known). For example, *see Sattison et al. [6]* for these initiating events for nuclear reactors, and NASA Guide [2] for space vehicles. The following procedures should be followed in this step of the PRA:

1. Select a method for identifying specific operational and nonoperational initiating events. Two of the representative methods are functional hierarchy and FMEA. If a generic list of initiating events is available, it can be used as a supplement.
2. Using the method selected, identify a set of initiating events.

3. Group the initiating events having the same effect on the system; for example, those requiring the same mitigating functions to prevent hazard exposure are grouped together.
4. Develop a systemic event tree for each initiating event, delineating the success conditions, initiating event progression phenomena, and end effect of each scenario.

For specific examples of scenario development, see [2–4].

Sequence or Scenario Development

The goal of scenario development (*see Managing Infrastructure Reliability, Safety, and Security; Environmental Exposure Monitoring; Dynamic Financial Analysis*) is to derive a complete set of scenarios that encompasses all of the potential exposure propagation paths that can lead to loss of containment or confinement of the hazards, following the occurrence of an initiating event. The scenarios that describe the functional response of the process to the initiating events are frequently displayed by event trees. The event-tree (*see Systems Reliability; Expert Judgment; Digital Governance, Hotspot Detection, and Homeland Security*) development techniques are discussed in [2–4].

In PRA, two types of event trees can be developed: functional and systemic. The functional event tree uses mitigating functions as its heading. The main purpose of the functional tree is to better understand the scenario of events at an abstract level, following the occurrence of an initiating event. The functional tree also guides the PRA analyst in the development of a more detailed systemic event tree. The systemic event tree reflects the scenarios of specific events (specific human actions, protective or mitigative subsystem operations, or failures) that lead to a hazard exposure. Therefore, a systemic event tree fully delineates the overall system response to an initiating event and serves as the main tool for further analyses in the PRA. For detailed discussion on specific tools and techniques used for this purpose, see Modarres [7]. The following procedures should be followed in this step of the PRA:

1. Identify the mitigating functions for each initiating event (or group of events).
2. Identify the corresponding human actions, systems, or hardware operations associated with each function, along with their necessary conditions for success.
3. Develop a functional event tree for each initiating event (or group of events).

Logic Modeling

Event trees commonly involve branch points at which a given subsystem (or event) either works (or happens) or does not work (or does not happen). Sometimes, failure of these subsystems (or events) is rare and there may not be an adequate record of observed failure events to provide a historical basis for estimating frequency of their failure. In such cases, other logic-based analysis methods such as fault trees or master logic diagrams may be used, depending on the accuracy desired. The fault-tree analysis involves developing a logic model (*see Early Warning Systems (EWSs) for Predicting Financial Crisis; Expert Elicitation for Risk Assessment*) in which the subsystem is broken down into its basic components or segments for which adequate data exist. For more details about fault trees associated to the event headings of an event tree, see Modarres *et al.* [8]. The following procedures should be followed as a part of developing the fault tree:

1. Develop a fault tree for each event in the event-tree heading for which actual historical failure data does not exist.
2. Explicitly model dependencies of a subsystem on other subsystems and intercomponent dependencies (e.g., common-cause failures). For common-cause failures, see Mosleh *et al.* [9].
3. Include all potential reasonable and probabilistically quantifiable causes of failure, such as hardware, software, test and maintenance, and human errors, in the fault tree.

The following steps should be followed in the dependent failure analysis:

1. Identify the hardware, software, and human elements that are similar and could cause dependent or common-cause failures.
2. Items that are potentially susceptible to common-cause failure should be explicitly incorporated

into the corresponding fault trees and event trees of the PRA where applicable.

3. Functional dependencies should be identified and explicitly modeled in the fault trees and event trees.

Failure Data Collection, Analysis, and Performance Assessment

A critical building block in assessing the reliability and availability of complex systems is the data on the performance of its barriers to contain hazards. In particular, the best resources for predicting future availability are past field experiences and tests. Hardware, software, and human reliability data are inputs to assess performance of hazard barriers, and the validity of the results depends highly on the quality of the input information. Collection of the various failure data consists fundamentally of the following steps: collecting generic data, assessing generic data, statistically evaluating facility-specific or overall system-specific data, and developing failure probability distributions using test and/or facility-specific and system-specific data. Three types of events identified during the risk scenario definition and system modeling must be quantified for the event trees and fault trees to estimate the frequency of occurrence of sequences: initiating events, component failures, and human error.

Typically, the necessary data include time of failures, repair times, test frequencies, test downtimes, and common-cause failure events (*see Systems Reliability; Reliability Data; Common Cause Failure Modeling*). Further uncertainties associated with such data must also be characterized. Kapur and Lamberson [10], Modarres *et al.* [8], and Nelson [11] discuss the methods available for analyzing data to obtain the probability of failure or the probability of occurrence of equipment failure. Also, Crow [12] and Ascher and Feingold [13] discuss analysis of data relevant to repairable systems. Finally, Mosleh *et al.* [9] discuss the analysis of data for dependent failures, Poucet [14] reviews human reliability issues (*see Human Reliability Assessment; Influence Diagrams*), and Smidts [15] examines software reliability models. Establishment of the database to be used will generally involve collection of some facility-specific or system-specific data combined with the use of generic performance data when specific data are absent or sparse. For example, [16–18] describe generic data

for electrical, electronic, and mechanical equipment. The following procedures should be followed as part of the data analysis task:

1. Determine generic values of material strength or endurance, load or damage agents, failure times, failure occurrence rate, and failures on demand for each item (hardware, human action, or software) identified in the PRA models. This can be obtained either from facility-specific or system-specific experiences, from generic sources of data, or both.
2. Gather data on hazard barrier tests, repair, and maintenance data primarily from experience, if available. Otherwise use generic performance data.
3. Assess the frequency of initiating events and other probability of failure events from experience, expert judgment, or generic sources.
4. Determine the dependent or common-cause failure probability for similar items, primarily from generic values. However, when significant specific data are available, they should be primarily used.

Quantification and Integration

Fault trees and event trees are integrated and their events are quantified to determine the frequencies of scenarios and associated uncertainties in the calculation of the final risk values. This integration depends somewhat on the manner in which system dependencies have been handled. We describe the more complex situation, in which the fault trees are dependent, i.e., there are physical dependencies (e.g., through support units of the main hazard barriers such as those providing motive, proper working environment, and control functions).

Normally, the quantification will use a Boolean reduction process to arrive at a Boolean representation for each scenario. Starting with fault-tree models for the various systems or event headings in the event trees, and using probabilistic estimates for each of the events modeled in the event trees and fault trees, the probability of each event-tree heading (often representing failure of a hazard barrier) is calculated (if the heading is independent of other headings). The fault trees for the main subsystems and support units (e.g., lubricating and cooling units and power units) are merged where needed, and the equivalent Boolean

expression representing each event in the event-tree model is calculated. The Boolean expressions are reduced to arrive at the smallest combination of basic failure events (the so-called minimal cut sets) that lead to exposure of the hazards. The minimal cut sets for the event-tree event headings are then appropriately combined to determine the cut sets for the event-tree scenarios. If possible, all minimal cut sets must be generated and retained during this process; unfortunately, in complex systems and facilities this leads to an unmanageably large collection of terms and a combinatorial outburst. Therefore, the collection of cut sets are often truncated (i.e., probabilistically small and insignificant cut sets are discarded on the basis of the number of terms in a cut set or on the probability of the cut set).

Even though the individual cut sets discarded may be several orders of magnitude less probable than the average of those retained, the large number of them discarded may sum to a significant part of the risk. The actual risk might thus be larger than what the PRA results indicate. This can be discussed as part of the modeling uncertainty characterization. Detailed examination of a few PRA studies of very complex systems, for example, nuclear power plants, shows that cut set truncation will not introduce any significant error in the total risk assessment results (see Dezfuli and Modarres [19]).

Other methods for evaluating scenarios also exist that directly estimate the frequency of scenario without specifying cut sets. This is often done in highly dynamic systems whose configuration changes as a function of time leading to dynamic event tree and fault trees (see **Canonical Modeling**). For more discussion on these systems, see Chang *et al.* [20], NASA Procedures PRA Guide [2], and Dugan *et al.* [21]. Employing advanced computer programming concepts, one may also directly simulate the operation of parts to mimic the real system for reliability and risk analysis (see Azarkhail and Modarres [22]). An example of PRA for compressed natural gas safety is presented in Chamberlain and Modarres [23]. Interested reader is also referred to Modarres [7] for a handful of numerical examples on PRA in a wide range of applications. The following procedures should be followed as part of the quantification and integration step in the PRA:

1. Merge corresponding fault trees associated with each failure or success event modeled in the

event-tree scenarios (i.e., combine them in a Boolean form). Develop a reduced Boolean function for each scenario (i.e., truncated minimal cut sets).

2. Calculate the total frequency of each sequence, using the frequency of initiating events, the probability of barrier failure including contributions from test and maintenance frequency (outage), common-cause failure probability, and human error probability.
3. Use the minimal cut sets of each sequence for the quantification process. If needed, simplify the process by truncating on the basis of the cut sets or probability.
4. Calculate the total frequency of each scenario.
5. Calculate the total frequency of all scenarios of all event trees.

Uncertainty Analysis

Uncertainties are part of any assessment, modeling, and estimation. In engineering calculations, we routinely ignore the estimation of uncertainties associated with failure models and parameters, because the uncertainties are very small and more often analyses are done conservatively (e.g., by using high safety factor, design margin). Since PRAs are primarily used for decision making and management of risk, it is critical to incorporate uncertainties in all facets of the PRA.

In PRAs, uncertainties are primarily shown in the form of probability distributions. For example, the probability of failure of a subsystem (e.g., a hazard barrier) may be represented by a probability distribution showing the range and likelihood of risk values.

The process involves characterization of the uncertainties associated with frequency of initiating events, probability of failure of subsystems (or barriers), probability of all event-tree headings, strength or endurance of barriers, applied load or incurred damage by the barriers, amount of hazard exposures, consequences of exposures to hazards, and sustained total amount of losses. Other sources of uncertainties are in the models used – for example, the fault-tree and event-tree models, stress-strength and damage-endurance models used to estimate failure or capability of some barriers, probabilistic failure models of hardware, software, and human, correlation between amount of hazard exposure and the consequence,

exposure models and pathways, and models to treat inter- and intrabarrier failure dependencies. Another important source of uncertainty is incompleteness of the risk models and other failure models used in the PRAs.

Once uncertainties associated with hazard barriers have been estimated and assigned to models and parameters, they must be “propagated” through the PRA model to find the uncertainties associated with the results of the PRA, primarily with the bottom-line risk calculations, and with the list of risk significant elements of the system. Propagation is done using one of the several techniques, but the most popular method used is Monte Carlo simulation (*see Risk Measures and Economic Capital for (Re)insurers; Simulation in Risk Management; Expert Elicitation for Risk Assessment; Reliability Optimization*). The results are then shown and plotted in the form of probability distributions. Steps in uncertainty analysis include the following:

1. Identify models and parameters that are uncertain and the method of uncertainty estimation to be used for each.
2. Describe the scope of the PRA and significance and contribution of elements that are not modeled or considered.
3. Estimate and assign probability distributions depicting model and parameter uncertainties in the PRA.
4. Propagate uncertainties associated with the hazard barrier models and parameters to find the uncertainty associated with the risk value.
5. Present the uncertainties associated with risks and contributors to risk in an easy way to understand and visually straightforward to grasp.

Sensitivity Analysis

Sensitivity analysis is the method of determining the significance of choice of a model or its parameters, assumptions for including or not including a barrier, phenomena or hazard, performance of specific barriers, intensity of hazards, and significance of any highly uncertain input parameter or variable to the final risk value calculated. The process of sensitivity analysis is straightforward. The effects of the input variables and assumptions in the PRA are measured by modifying them by several folds, factors, or even one or more order of magnitudes, one at a time,

and measure relative changes observed in the PRA’s risk results. Those models, variables, and assumptions whose change leads to the highest change in the final risk values are determined as “sensitive”. A good sensitivity analysis strengthens the quality and validity of the PRA results. Interested readers are referred to Modarres [7] for more detailed discussions on sensitivity analysis. The steps involved in the sensitivity analysis are as follows:

1. Identify the elements of the PRA (including assumptions, failure probabilities, models, and parameters) that analysts believe might be sensitive to the final risk results.
2. Change the contribution or value of each sensitive item in either direction by several factors in the range of 2–100. Note that certain changes in the assumptions may require multiple changes of the input variables. For example, a change in failure rate of similar equipment requires changing of the failure rates of all these equipment in the PRA model.
3. Calculate the impact of the changes in step 2, one at a time, and list the elements that are most sensitive.
4. On the basis of the results in step 3, propose additional data, any changes in the assumptions, use of alternative models, and modification of the scope of the PRA analysis.

Risk Ranking and Importance Analysis

Ranking the elements of the system with respect to their risk or safety significance is one of the most important outcomes of a PRA. Ranking is simply arranging the elements of the system on the basis of their increasing or decreasing contribution to the final risk values. The ranking process should be done with much care. In particular, during the interpretation of the results, since formal importance measures are context dependent and their meaning varies depending on the intended application of the risk results, the choice of the ranking method is important.

There are several unique importance measures in PRAs. For example, Fussell–Vesely [24], Birnbaum [25], risk reduction worth (RRW), and risk achievement worth (RAW) [8] are identified as appropriate measures for use in PRAs, and all are representative of the level of contribution of various elements

of the system as modeled in the PRA and enter in the calculation of the total risk of the system. Another important set of importance measures focus on ranking the elements of the system with respect to their contribution to the total uncertainty of the risk results obtained from PRAs. This process is called *uncertainty ranking* and is different from component, subsystem, and barrier ranking. In this importance ranking, the analyst is only interested to know which of the system elements drive the final risk uncertainties, so that resources can be focused on reducing important uncertainties.

For additional discussions on the risk ranking methods and their implications in failure and success domains, see Azarkhail and Modarres [26]. The following are the major steps of importance ranking:

1. Determine the purpose of the ranking and select appropriate ranking importance measure that has consistent interpretation for the use of the ranked results.
2. Perform risk ranking and uncertainty ranking, as needed.
3. Identify the most critical and important elements of the system with respect to the total risk values and total uncertainty associated with the calculated risk values.

Interpretation of Results

When the risk values are calculated, they must be interpreted to determine whether any revisions are necessary to refine the results and the conclusions. There are two main elements involved in the interpretation process. The first is to understand whether the final values and details of the scenarios are logically and quantitatively meaningful. This step verifies the adequacy of the PRA model and the scope of analysis. The second is to characterize the role of each element of the system in the final results. This step highlights additional analyses data and information gathering that would be considered necessary.

The interpretation step is a continuous process with receiving information from the quantification, sensitivity, uncertainty, and importance analysis activities of the PRA. The process continues until the final results can be best interpreted and used in the subsequent risk-management steps. The basic steps of the PRA results interpretation are as follows:

1. Determine accuracy of the logic models and scenario structures, assumptions, and scope of the PRA.
2. Identify system elements for which better information would be needed to reduce uncertainties in failure probabilities and models used to calculate performance.
3. Revise the PRA and reinterpret the results until attaining stable and accurate results.

Product Risk Management: Testing and Warranties

The main purpose of product testing is to identify and rectify defects in order to reduce unexpected failures in the field. Manufacturers employ various testing strategies during a product's life cycle to validate their product's design and gain insight into the product performance in a customer's environment. Product testing should be seen as a key ingredient for competitive advantage, as a thoroughly tested product will lead to high consumer satisfaction and market superiority. This article presents tests performed during the prototype and production phases. These testing methodologies are applicable to the manufacture of biomedical devices, computer hardware and peripheral equipment, semiconductor equipment, and consumer electronics, among other items.

Prototype Phase Testing

During the prototyping stage, engineers build working samples of the product they have designed. Design verification testing (DVT) is used on the prototypes to verify functionality against predetermined functional specifications and design goals. This information is used to validate the design or identify areas of the design that need to be revised. DVT is also used to ensure that any new functions introduced late in the product cycle do not adversely affect any previously available functions ("regression testing"). DVT marks the beginning of the design refinement phase in the design cycle. During this cycle, the design is revised and improved to meet performance requirements and design specifications. Highly accelerated life testing (HALT) provides a quick way to precipitate failures and reveal design weaknesses. HALT is often used only on high risk modules or key components. During the HALT process, the products are stressed with stimuli beyond the expected field environments to determine their operating and destruction limits. Initially, each stress is stepped up individually to the point of failure and, at the end of HALT, different stresses are combined to maximize their effects. Typical stresses used in HALT are thermal and vibration stress, rapid thermal transients, humidity, voltage

margin, and power cycles. The increased stress levels also provide a simulated aging effect on the product, so that failures that normally show up in the field only after a long time at the usual stress levels can be quickly discovered during HALT.

One important element of the HALT process is the root cause analysis to determine which failures are relevant and to evaluate their impact of the products in the field. If corrective actions can be implemented during testing, then the follow-on test would provide feedback on how effective the corrective actions are.

Time-to-failure data from HALT may be analyzed to draw inferences about product reliability. Product life is related to the stress level by an acceleration equation. This allows the manufacturer to extrapolate a reliability estimate for the working environment from units tested at intensified stress levels. The most frequently used models are the Arrhenius and Eyring models for temperature acceleration, and the power law model (Nelson [1], Meeker and Escobar [2], and NIST [3]) for voltage and vibration stresses.

Let X_s and X_u be two random variables representing the time to failure at stress and at use, respectively. Then, under a linear acceleration relationship between stress and use, we have $X_s = AF \times X_u$, where AF is a constant representing the acceleration factor.

In the Arrhenius model, which is based on the reaction rate of a failure causing chemical or physical process due to elevated temperature, the acceleration factor between a higher temperature T_2 and a lower temperature T_1 is given by

$$AF = \exp \left\{ \frac{\Delta H}{k} \left(\frac{1}{T_1} - \frac{1}{T_2} \right) \right\} \quad (1)$$

with temperatures T_1 and T_2 measured in kelvin and k denoting the Boltzmann's constant (8.617×10^{-5} in electronvolt per kelvin). The constant ΔH is the activation energy, the minimum energy necessary for a specific chemical reaction to occur. The value of ΔH depends on the failure mechanism and the material involved, and typically ranges from 0.3 or 0.4 up to 1.5 or higher. Applications of the Arrhenius model include battery cells and dielectrics.

The Eyring model, derived from quantum mechanics, includes stress due to elevated temperature and can be expanded to include other type of stresses. The temperature term is very similar to the Arrhenius

model, with the acceleration factor

$$AF = \left(\frac{T_1}{T_2}\right)^\alpha \exp \left\{ \frac{\Delta H}{k} \left(\frac{1}{T_1} - \frac{1}{T_2} \right) \right\} \quad (2)$$

The generalized Eyring model is used to model the situation where the device is subjected to two types of stresses, a thermal stress and a nonthermal stress, and is applicable in the accelerated testing of thin films. Let S_1 and S_2 denote two different levels of a nonthermal stress such as voltage or current. Then the acceleration factor is as follows:

$$AF = \left(\frac{T_1}{T_2}\right)^\alpha \exp \left\{ \frac{\Delta H}{k} \left(\frac{1}{T_1} - \frac{1}{T_2} \right) \right. \\ \left. + B(S_1 - S_2) + C \left(\frac{S_1}{T_1} - \frac{S_2}{T_2} \right) \right\} \quad (3)$$

The model parameters are α , ΔH , B , and C . As in the Arrhenius Model, k is Boltzmann's constant, ΔH is the activation energy, and temperatures T_1 and T_2 are measured in Kelvin. The parameter C is used to model the interaction between the thermal and nonthermal stresses. The model can also be expanded to include additional nonthermal stresses. Two more parameters are added to the model with each additional nonthermal stress.

The power law model uses voltage as the only stress and is a simplified version of the generalized Eyring model where $\alpha = \Delta H = C = 0$, $B = -\beta$ and the voltage stress is measured by $S = \ln(V)$. The acceleration factor is as follows:

$$AF = \left(\frac{V_1}{V_2}\right)^{-\beta} \quad (4)$$

The power law model is applicable for testing capacitors.

Throughout the prototype phase testing, problems are identified and corrective actions are taken, which may result in design revision. *Reliability growth* refers to the improvement of the product reliability over this period of time due to changes in the product's design. For example, Crow [4] modeled reliability growth processes for a complex repairable system and provided procedures for estimating the parameters of the underlying stochastic process. Let $N(t)$ denote the cumulative number of failures at time t . The intensity function $\rho(t) = d[EN(t)]/dt$ is constant for a time-homogeneous Poisson process. In the Crow model, the intensity function is $\rho(t) = \lambda\beta t^{\beta-1}$, i.e., a Weibull process (Finkelstein

[5]), owing to the fact that the time to first failure under this growth process has a Weibull distribution. Crow first developed the model at the US Army Material Systems Analysis Activity (AMSAA) and it is also known as the *Crow-AMSAA model*. The model has been widely adopted to model the reliability of semiconductor test equipment (Jin *et al.* [6]) and equipment reliability in commercial nuclear power plant (Sun *et al.* [7]). It is the standard model for repairable systems in the International Electrotechnical Commission (IEC) standards.

HALT and reliability growth analysis supply manufacturers with an initial reliability assessment derived from product testing, which can be combined with estimates from reliability prediction to forecast warranty costs while the product is still in the prototype phase. Manufacturers use reliability prediction during the product design and development period to evaluate the life expectancy of their products. Reliability prediction is relatively inexpensive and gives designers the capability to compare different concepts and designs in terms of reliability. Before the prototypes are built, this is their only means of setting product reliability goals and making competitive evaluations.

The most commonly used predictive models are based on either MIL-HDBK-217 or Telcordia SR-332, using only the parts count and parts type information from the product bill of material (BOM). MIL-HDBK-217 is a military handbook for reliability prediction of electronic equipment. It contains the failure rate for most part types such as ICs, transistors, diodes, capacitors, and connectors and is based on estimates from field data. The Telcordia Standard is a modification of MIL-HDBK-217 that allows the parts count data to be enhanced by laboratory test data and field performance data. It also provides a method for predicting failure rates during the first year of operation accounting for burn-in times and temperatures.

Production Phase Testing

At the start of volume production, product verification testing (PVT) is performed on the first few production units to demonstrate that the design has been correctly implemented in production. In contrast to the prototype phase testing, where subsystems may be tested separately, subsystems are integrated into a complete

system and tested in PVT. This may reveal interaction failure modes. Test results from PVT are analyzed to set the initial burn-in duration for volume production and to support key product checkpoints such as the early ship and general availability programs.

A reliability qualification test (RQT) is used to demonstrate the product reliability that was previously derived using reliability prediction during the design cycle. RQT is usually performed at the system level concurrent with or immediately after PVT. It is typically set up as an acceptance test. MIL-STD-781D provides the acceptance criteria and decision risks for various fixed-length and sequential test plans for products characterized by an exponential time-to-failure distribution. To shorten the test duration, RQTs are occasionally run as an accelerated test. This may be accomplished by simply increasing the duty cycle from the end-use environment. The basic assumption made in this type of accelerated test is that the product does not deteriorate while in standby mode. In more complex situations, test engineers will rely on the HALT results to determine the types of stresses, stress levels, and acceleration factor to apply in RQT.

The highly accelerated stress screen (HASS) is used to precipitate early failures in production using a stress screen. Initially, the screen profile is developed on the basis of the failure modes detected in HALT. The test engineer then runs a sample of products through multiple passes of the proposed screen. If a failure occurs, stress levels are reduced to calibrate the safety of the screen. Once the product is released, field performance is monitored to ensure that all observed failure mechanisms are accounted for in HASS. Early life failures in the field may indicate a need to refine the stress screen in HASS. Field returns that are diagnosed as “no problem found” (NPF) are often tested under the HASS screen to confirm that it can detect intermittent design problems. Once the manufacturing process is stabilized and the defect rate in HASS is under control, HASS is replaced by a highly accelerated stress audit (HASA) program. HASA implements the same screens as HALT, but only on a sample basis. HASA results are regularly analyzed to see if there is a need to change the sample size of the audit.

An ongoing reliability test (ORT) is used to monitor a product on a continual basis and obtain a reliability estimate by testing samples of the production units. ORT is similar to the RQT except that the RQT is performed only once prior to release of the product,

whereas the ORT is an ongoing test, performed by rotating in samples from the manufacturing line. As an ongoing test, ORT can detect changes in failure modes and product reliability caused by design or manufacturing process changes.

Warranty Analysis

Warranty costs have an enormous impact on business profitability. Warranties are driven by service support, material, failure analysis, inventory, and logistics costs. They incur expenses across multiple organizations within a company. Warranty analysis (see **Warranty Analysis**) is used to identify the most likely warranty events and develop strategies for cost reduction.

During product development, warranty analysis is performed by using the reliability prediction results to set up a cost model that examines the trade-offs between design, service, and warranty policies. Reliability prediction identifies the most likely warranty events, and the projected warranty costs are calculated for each identified event. As an alternative to reliability prediction, some manufacturers may choose to use a current product in the same market segment with similar design and function as an internal benchmark. The cost analysis can identify the key contributors to the warranty budget, such as product failure rates and support processes. The results are used to evaluate alternative designs and support strategies. They also establish a preliminary requirement for logistics support on issues such as spare parts inventory and field personnel.

Later in the design phase, prototype test results are utilized to update the reliability estimates and refine the cost model. Cost analysis can confirm whether sufficient testing has been carried out. HALT results are used at this stage to develop diagnostic tools so that the support organization may service the warranty events more efficiently in order to reduce the overall warranty cost.

During the product design and development stage, warranty analysis is built around activities for forecasting liabilities associated with future warranty claims. The actual warranty costs are found only after product launch, by tracking shipments and warranty return data. Most manufacturers have a field failure tracking system that documents the returned material by returned date, part number, manufacture date and

location, and failure diagnostics for a given product. This data is used to evaluate the product reliability and warranty cost exposure over the life of the warranty. After the product is released to the field, a sustaining engineering organization is responsible for the update of the product design, introduction of new materials to be used on the product, and the revision of product, process, and test specifications. Sustaining engineering analyzes the field failure data regularly to discover changes in failure modes over time and revise the HASS screen accordingly. In a product recall situation, the field failure data are examined to see if the problem can be isolated to a specific manufacture location and a narrow range of manufacture date. As a result, the company may be able to reduce a costly large-scale recall to a smaller isolated replacement program.

Professional Organizations in Risk Management

Defining Financial Risk Management

Financial risk management (*see Solvency; Extreme Value Theory in Finance*) can be as broadly or as narrowly defined as the professional organization wants it to be. There is no globally accepted definition. It changes depending on who you are speaking with, where in the world the conversation takes place, what day it is during the calendar year, and the interests of those engaged in discussion.

The Global Association of Risk Professionals (GARP) defines financial risk management to include credit, market, and operational risk theories, concepts, and practices in addition to the quantitative aspects associated with each area. Each of these areas of financial risk management can cover specific subjects that are so broad in scope or so complex in nature that many financial risk-management practitioners specialize in them alone, or even a subsection within that particular subject area.

Included in GARP's financial risk definition would be activities engaged in by a wide variety of organizations such as banks, securities firms, asset management firms, pension funds, insurance companies, and in many instances supervisors or regulators. Each of these organizations individually will have unique risk-management issues to address and their internal definition of financial risk management will take on broadly different overtones by country, region, industry, company, department, or product line, or a combination of any or all of these geographical or corporate characteristics. These varied approaches to financial risk management and the sheer complexity of attempting to respond to the needs of a widely dispersed clientele present material challenges to any financial services professional organization.

The Role of a Professional Organization

As with the definition of financial risk management, the role of a professional organization within the field of financial risk management will vary

widely. Professional organizations obviously represent different membership constituencies, an important and major distinguishing factor among professional organizations.

Certain organizations include only corporations as members, while others will have only individuals who have joined personally, with or without the support of their employers. Some will combine the two membership types but understandably end up bifurcating services and service levels depending on who is paying the bills.

There are pros and cons associated with each type of membership organization. For example, a corporate-only membership may consist of a sterling list of members with each paying a yearly fee based on size. In those types of professional organizations, the corporate members will generally view their membership fee as an initial payment for programs offered by the association, expecting to be charged a below market rate, or no charge, for programs offered by the organization. Many corporate members will also expect to be represented on the organization's board and as members of any of the association's working groups. All of these expectations can be very positive for the association and its members. The primary issue to be concerned about with this structure is whether the association can remain nimble, being able to respond to issues and implement new initiatives in a timely manner without having to deal with a large committee and approval process.

Organizations such as GARP have individuals as their core membership. These individuals join on their own or with their employer's sponsorship. The advantage of this type of organizational structure is that the association can be quickly responsive to changes in the industry as the decision-making process is much quicker. In addition, because the individuals who have joined have done so on their own, their level of interest is generally exceptional, allowing for a large pool of individuals that would be available to assist in moving the association's programs forward.

Professional Organization Services

Educational services are generally the primary focus of most professional organizations. In the financial services industry this role is especially important given the number of new initiatives regularly being

put forth by regulators and the dynamic nature of the industry and its seemingly insatiable desire and ability to invent new products and services.

Educational services can take the form of offering professional certification programs, courses and workshops, conferences and events, and take on the role of educating regulators and assisting in the development of legislative or regulatory initiatives.

Professional certification programs are growing dramatically. This is the result of the increasing complexity of the financial services industry and the need to ensure that those who are working in certain subject areas can do so competently and with a knowledge base that is up-to-date and represents globally accepted approaches.

The rapid globalization of the financial services industry has enhanced the need to ensure that those in the financial services industry are speaking in terms that are common across borders and which represent accepted industry practices. A failure to do so will quickly result in misunderstandings or errors that will rapidly lead to financial and reputation risk.

Lobbying is another form of educational service. Not all organizations engage in lobbying activities, and for those it is a specific part of their mission.

The concept of lobbying is viewed differently in different parts of the world. In the United States it commonly incorporates the hiring of individuals whose primary purpose is to directly influence the votes of government legislators and other regulators as they look to decide specific issues or issues. In other regions it may include the provision of advice to legislators or regulators but not with the objective of forming the wording for a specific initiative that would benefit a specific group or organization.

GARP includes with its educational activities the role of being an industry voice for reviewing and providing insight into the effects of legislative or regulatory initiatives on financial institutions. This role is one of education and dialog encouragement among and between regulatory bodies and industry practitioners rather than the wielding of direct influence in specifically determining the wording for or effect of a rule or regulation. This is done through the formation of industry working groups whose purpose is to review issues of importance to the financial services industry as a whole and through written and oral discussion recommend approaches that would be in the best interests of the financial services industry.

Other organizations may define their role as it relates to lobbying differently. For example, the United States based Securities Industry and Financial Markets Association is a very effective lobbying organization that works on behalf of its institutional membership to influence regulatory initiatives. This is an important and material part of its mission, along with certain other educational activities.

Lobbying on behalf of an organization's membership is a form of financial risk management. For example, an organization seeking to establish standards relating to structured financial products or the adoption of approaches to influence capital allocation inherently includes in its analysis a number of financial risk-management concepts. Lobbying is intended to influence the development of rules and regulations by which every organization must operate, and as such it has direct risk-management implications.

Networking is another important role played by a professional risk-management organization. This role is simply one of providing a forum for risk professionals either by city, region, or country to share ideas and best practices. These networking professional organizations play an essential role for the sharing of career-related information and for offering professional development opportunities among their members.

Still, other financial associations have adopted a hybrid model, taking on the role of an educational institution and networking forum, a lobbying and educational group, or an organization that seeks to establish best practices through the issuance of "white papers" while not directly lobbying on behalf of its members. These latter organizations attempt to influence the thinking of rule-making bodies through the submission of formal letters expressing opinions to government regulatory bodies or publishing papers approved by the majority of its members.

Each membership model will have a direct effect on the organization's business approach and the organization's governance. In turn that will determine the latitude it may have in addressing new markets, issues, and responding to member requests.

There does not appear to be any one ideal model in terms of networking, lobbying, education, or a combination thereof, nor is there one prevailing membership model. Most organizational business models have evolved over time with regard to their scope of activities and membership structure. However, the rapid globalization of the marketplace is starting to

take a toll on some of these historical models. It is forcing many professional organizations to redefine their roles and services. But, unfortunately, it is leaving many with limited options for a variety of reasons.

Many organizations were slow to respond to the changing marketplace, allowing others to expand their services and/or leapfrog over them and take the spot as the global contact for that particular profession. There is, in most cases, little need to have two or more organizations providing the same or similar services to the same group of professionals.

In other cases corporate charters, which were viable when first put into place, now restrict their expansion outside certain geographic boundaries. For others, the need on the part of their membership for services that reflect global references and understanding cannot be fulfilled by a purely regional or local organization.

Professional Organizations as a Business

As noted above, the individual roles of professional organizations can be varied. They can be broad and cater to a global constituency or they can be narrow by responding to only a local market niche.

In a world where new financial products are being developed daily, where financial issues are becoming more complex by the day, and where it is virtually impossible to move away from having to consider issues based in a broader global context, each organization must be run as a business. This is a point missed by many professional organizations and their membership. Professional organizations are no different from any other business entity other than the fact that they, in most cases, do not have formal equity holders – their shareholders are their members.

Professional organizations must provide relevant services just as any other business entity. Whether the organization is supported by a dues paying individual or corporate membership, or its revenues are derived from the providing of a value-added service where the failure of its membership and/or the public to purchase the service will directly affect the organization's revenues, any professional organization must carve out its market niche and provide exceptional service. A failure to do so, as with any other business organization, will result in a diminished reputation and a diminution of the

financial resources necessary to run the organization and provide new and/or improved services.

Providing relevant services is now becoming a material issue for many organizations. Historically professional organizations have been able to service their membership by focusing on the markets that make up their region or local community, rightly gearing their product toward what would be of benefit to their direct membership. Now, however, their membership is being impacted by the rapid globalization of the financial marketplace and the instantaneous availability of information made possible by, among other sources, the Internet.

Global issues are now finding their way into virtually any financial risk-management conversation. The result is that many professional organizations' members are seeking information on how to compete and/or respond to local or regional issues by using globally accepted approaches. Local professional organizations are finding it difficult or impossible to respond. They have to consider expanding their mandates beyond their local coverage and/or choosing a subject area they can respond to given the broad financial risk marketplace. Unfortunately many local professional organizations will not have the legal ability to expand their activities, personnel well versed in international issues, or the financial ability to develop globally based programs.

The above issues are causing professional financial risk organizations to think of developing alliances with other professional organizations that will complement their business model and respond to their members' needs. However, these alliances are fraught with their own issues. Some issues are simply financial related while others are directly affected by the need to manage these relationships and the time that it requires. With many professional organizations working with limited budgets, the challenges presented are daunting.

This article is not intended to suggest that the time has come to minimize "local" professional organizations. What is being suggested is that it will become increasingly difficult for a professional organization without a global mandate to ultimately develop one. There are barriers to entry for professional organizations as well as for corporations. There are few compelling reasons for one professional organization to compete with another professional organization, especially if the organization that has the global experience is doing a good job. In fact, there are

material reasons for this not to occur given the general not-for-profit or charitable business models followed by most professional organizations.

The Role of the Professional Organization

The role of the professional risk-management organization is evolving, as is the profession of financial risk management. However, it is clear that a professional risk-management organization should possess a number of attributes.

Any professional organization should be independent. Independence is more than just legal separation from various parties. It means that it should not be influenced directly or indirectly by third parties who are attempting to market their products or promote their own agendas. Products and/or services offered as a means to ensure an individual has gained a certain professional standing should not be the subject of outright paid endorsements by third parties, or if they are the relationship(s) must be fully disclosed. Anything less should be considered a conflict of interest.

An organization's committee structure and board should not consist of members who are "interested parties", meaning whose vote on a decision could result in positive benefits accruing to them or their firm, unless there is full disclosure either directly or indirectly through the rationale behind the organization's formation.

Corporate governance is just as important to professional organizations as it would be to any other corporate entity. There are strong arguments that a sound corporate governance structure is even more important to a professional organization as by its nature it is supposed to represent leadership in its chosen field. The governance structure of all professional organizations should be open, transparent, and subject to review by its board and/or executive committee, with its membership kept regularly informed of material financial and structural issues.

Conflicts of interest must be carefully considered and monitored. For example, organizations offering professional designations should be careful that the certifying activity is not compromised by the offer of a product or service that would directly or indirectly benefit individuals who are charged with setting the standards for that designation. In many instances, apparent conflicts of interest can be just as damaging as actual conflicts. Professional organizations should

be held to a higher standard as they are effectively role models to their members and the industry they represent.

A professional organization should seek excellence in all it does. It exists to serve its membership. Its members are relying on the organization as a forum to share ideas and learn about new products and/or approaches to issues. In most cases these members rely on the organization to be the expert in its chosen field, presenting well-developed and unbiased views of issues and concepts.

An industry representative professional organization should take a practice-orientated approach to issues and concepts. It needs to develop and share information that will assist its members in doing their everyday job better. Professional organizations in risk management play a major role in educating their members. This education must take into consideration the fact that its members are seeking to not only keep up with advances but also that they are working full time in their roles. Presenting succinct programs that are practical and thought provoking or broadening in scope should be high on the organization's agenda.

Bridging the gap between academia and the everyday working world is an agenda item that should also rate high in most organizations. Academics through their research and teaching activities offer to the professional practitioner community a valuable resource of new ideas and approaches, concepts that, for the most part, risk management or other professional practitioners will not have the time to develop owing to their own daily activities. This academic/practitioner sharing can benefit both groups of professionals and should be encouraged through the professional association's activities.

Conclusion

Professional organizations in risk management are playing an increasingly important role in educating professionals and industry regulators. They also serve as a bridge between geographic locations, allowing for a sharing of resources and programs to assist financial service practitioners having a need to gain knowledge and understanding of how markets work in different parts of the world. The networking opportunities offered to their membership are just as important as these will allow for an informal and free sharing of ideas that should help

any practitioner in his or her daily activities. Most importantly, professional organizations must operate as any other business developing programs that are of the highest quality, innovative, and informative. It is these organizations that will independently provide

the foundation for the establishment of a culture of risk awareness throughout the world.

RICHARD APOSTOLIK

Protection of Infrastructure

Critical infrastructure (*see* **Managing Infrastructure Reliability, Safety, and Security; Game Theoretic Methods**) consists of physical and information technology facilities, networks, services, and assets that are essential to the well-being, operations, and continuity of operation of a country. They include, but are not limited to, agriculture and food, public health, telecommunications, banking and finance, transportation, water and power systems, emergency services, government, waste removal, and the industrial base.

Risk assessment for critical infrastructure has two components: assessment of the likelihood of particular disruptions from either natural or man-made disasters, and the evaluation of the consequence from that disruption. There are many metrics by which decision makers assess the consequences arising from the failure of a critical infrastructure: (a) human health and safety (e.g., in terms of the number of lives lost or placed at risk), (b) economic (e.g., in terms of the recovery cost, or the cost of lost business, or both), and (c) environmental (e.g., cleanup costs). There are also vaguer metrics, relating to sociopolitical damages and national security perception.

Although the consequence assessment can be cast as in a multiattribute utility function (*see* **Multiattribute Modeling; Multiattribute Value Functions**) framework, this is not usually the primary concern. Policy makers have good intuition about outcomes that are highly problematic, and delicate trade-offs among these do not drive their decisions. The main problem concerns the probability of such outcomes, and that is the focus in this article: the methodology of risk assessment for critical infrastructure.

Often one can rely on historical data to assess the likelihood of occurrence of natural disasters, such as earthquakes, hurricanes, floods, or failure in the power grid (assuming that the secular trends in these are slow or negligible, which is sometimes questionable). In contrast, assessing the likelihood of a terrorist attack or a complex engineering failure is harder because only a few incidences have occurred and because the causal factors are poorly understood. Often, risk analysts distinguish “aleatory” probabilities from “epistemic” probabilities. The former refer to events that are well

described by laws of probability, such as the actuarial rate of automobile accidents. The latter refer to events that have probability mechanisms that are poorly understood, such as the probability that a specific driver will have an accident (this is clearly affected by many unknowns, such as the experience, sobriety, and amount of driving that person will do).

For epistemic applications, it is often only possible to rank order the relative likelihood of potential scenarios, as informed by such tools as scientific models, psychological reasoning, and game theory. All three contribute to estimating the risk of a bioterrorist attack; medical science gives guidance on how easily a specific pathogen could be used, psychological reasoning indicates what kinds of people might be likely to mount such an attack, and game theory describes the interplay of countermeasures and attack strategies in terms of reducing the level of risk.

Understanding the likelihood and consequence of disruptions are essential for rational allocation of finite resources to protect high value infrastructure and to distribute assets to help speed recovery after an event. In terrorist situations, making these estimates is the responsibility of the Office of Infrastructure Protection (OIP) of the Department of Homeland Security (DHS). For nonterrorist threats, responsibility is typically shared among various federal and state agencies, with the Federal Emergency Management Agency (FEMA) having a special role in disaster response.

Modeling the Risk of Rare Events

There is a large and straightforward literature on modeling the occurrence of small to medium natural disasters using standard extreme value theory (*see* **Large Insurance Losses Distributions; Extreme Value Theory in Finance; Mathematics of Risk and Reliability: A Select History**). The approach relies upon fitting the tail behavior of distributions (*cf.* [1], for a discussion in the context of insurance). There are a number of standard procedures for specific situations, largely growing from the work of Pickands [2] on extreme order statistics. Of course, the entire field is strongly influenced by the work of Gumbel [3] and Fisher and Tippett [4], who established that there are only three possible asymptotic distributions for the maxima or minima of a set of independent random variables.

However, the risk of extreme natural disasters (sometimes called *low-probability, high-consequence events*) are harder to model. The same holds true for failures of complex technological systems that should not fail, such as a nuclear power plant and/or both space shuttle disasters. The Boxing Day tsunami, the Three Miles Island nuclear accident, and the failures of the Columbia and Challenger, all support the view that the statistical and scientific models used at that time grossly underestimated the actual risk.

To do risk assessment for low-probability, high-consequence events, most analysts attempt to combine expert judgment with a decomposition of the problem into constituent elements. Different sets of experts may be consulted about the different elements (which can create problems, since there is a heuristic in the field that most failures occur at the interfaces between the elements in a complex system). The hope is that the judgment of domain experts can partially overcome the lack of historical data. However, this hope often founders because experts tend to be overconfident of their opinions (and thus understate the true uncertainty) because elicitation techniques (see **Imprecise Reliability; Bayesian Statistics in Quantitative Risk Assessment; Expert Judgment; Multiattribute Modeling**) are technically difficult to implement correctly (cf. [5]), and because the problem of combining expert judgments is hard (the best answer may come from a single expert in the pool who has correctly apprehended something that the others overlooked). So use of expert judgment is difficult, but in general there is no practical alternative.

Similarly, it can be problematic to divide a complex system into its functionally distinct elements. A common strategy decomposes the system into its subsystems and components tied together by a fault tree (see **Systems Reliability; Fault Detection and Diagnosis; Probabilistic Risk Assessment**) (cf. [6]), or more generally, by a Bayes net (cf. [7]). In the absence of pertinent historical information, the Bayes net is populated using expert knowledge. In this context, the problem of combining expert knowledge has prompted the exploration of several alternative uncertainty quantification paradigms, including fuzzy logic (see **Early Warning Systems (EWSs) for Predicting Financial Crisis**), Dempster–Shaffer belief functions, and probability intervals (the authors of this article deliberately give no citations to this literature, since we do not endorse these approaches for any application – the methods do not provide

the coherent framework for uncertainty quantification that is provided by probability theory). A more appropriate strategy for quantifying the uncertainty in the experts’ judgments of the conditional probabilities in a Bayesian network is to model these probabilities as random variables (but this is not simple to implement). The advantage of this approach is that inference relies on the rules of probability while, at the same time, one can accommodate the uncertainty inherent from the expert elicitation.

The problem of determining such things as the risk of a terrorist event is even harder than predicting the failure of a complex engineered system because of the need to model political forces (causes of origin, politics, and social-cultural basis) and human behavior (terrorist organizational structure, activity, and terrorism effects). The risk assessment is further compounded by the evolving nature of terrorism, and the fact that terrorist groups range from lone wolves to rogue nations. As a result, any risk assessment in this area relies heavily upon judgments from many kinds of social scientists.

The Terrorism Risk Insurance Act (TRIA) of 2002 created a federal “backstop” for insurance claims related to acts of terrorism. The TRIA was intended as a temporary measure to allow time for the insurance industry to develop their own solutions and market new products to insure against acts of terrorism. The renewal of the TRIA act in 2005 is an indication of the difficulty the insurance companies have had in evaluating the risk associated with terrorism.

Infrastructure Interdependencies

Historically, individual infrastructures have been modeled as physically and logically separate systems, and so was the modeling of the impact of disruptions to each infrastructure. But in reality, as a result of advances in information technology and the necessity of improved efficiency, the various infrastructures have become increasingly automated and interconnected, linked by people, energy, and information. For example, a disruption in the transportation sector impacts all other sectors by limiting the ability of individuals to get to work. Or a disruption of the power grid can impact the telecommunication sector, which in turn adversely affects the banking sector. The spatial–temporal scale of the interaction depends on the type of interconnection (human, energy, and information) between the infrastructures.

These interdependencies also are responsible for new vulnerabilities, ranging from equipment failure, human error, weather and other natural causes, to physical and cyberattacks that were not previously taken into account. Furthermore, such interdependencies have the potential of generating feedback loops that can exacerbate the impact of the original disruption. As a result, modern risk assessment of critical infrastructures must model these interdependencies to effectively assess the consequence of disruption.

These models for interdependency simulate the dynamics of individual infrastructures and couple separate infrastructures to each other according to known connections. This tool enables analysts to model the cascading effect associated with a particular failure. For example, repairing damage to the electric power grid in a city requires transportation to failure sites and delivery of parts, fuel for repair vehicles, telecommunications for problem diagnosis and coordination of repairs, and the availability of labor. The repair itself involves diagnosis, ordering parts, dispatching crews, and performing repairs. The electric power grid responds to the initial damage and to the completion of repairs with changes in its operating characteristics, such as the number of megawatts that can be distributed to customers. The dynamic within and between infrastructure sectors are modeled by differential equations, discrete events, and codified rules of operation, and may involve as many as 5000 variables, many of which are output metrics estimating the human health, economic, or environmental effects of disturbances to the infrastructures.

Agent-based modeling and simulation (ABMS) is a tool of increasing interest for the analysis of large-scale complex systems that consist of a large number of subsystems (agents) which interact with each other and with their environment (*cf.* [8]). Sociotechnical simulations form a particular set of simulation tools that models human interaction with one another and their surroundings. The overall dynamic behavior of the resulting complex system typically emerges in a nonobvious manner from the simpler interactions among subsystems of the system. Many users feel these models are more robust and transparent than the systems of differential equations that are also popular.

As an example of a sociotechnical simulation, consider TRANSIMS, a transportation model (*see Homeland Security and Transportation Risk*) developed at the Los Alamos National Laboratory. For that simulation, one starts out by creating a

synthetic population of households whose demographic characteristics match the census data. Using data from the National Household Travel Survey [9], one assigns a set of activities to each household, together with the location for the assigned activities. The agents (humans) interact with one another when traveling from one location to another on the road network. Such simulation has been shown to give realistic traffic patterns and has been used to predict the impact of adding public transportation or new highways to an existing road network.

In the context of infrastructure protection, TRANSIMS has been used to predict the effect of road and bridge closures. Since other sectors require workers (e.g., the health sector needs doctors and nurses), variations of this tool can model the interdependence between the transportation infrastructure and other infrastructures. The strength of sociotechnical models is that they can describe the demand for resources imposed by the various infrastructure sectors. For example, TRANSIMS allows the tracking of all the cell phones in a city, thereby representing realistic spatial-temporal demand for mobile telecommunications.

Recent work on infrastructure interdependence has identified two new areas that are attracting attention. Both concern optimal investment strategies for protecting infrastructure.

Consider a decision maker who wants to protect a city and has a limited budget to do so. Some investments, such as hardening the city's levee system, will protect only against hurricanes and floods. Other investments, say in hospitals and emergency housing, provide a smaller degree of protection against a larger set of threats, not only hurricanes and floods, but also fires, explosions, and pandemic flu. Managers have to balance these trade-offs, but often the decision-making structures prevent effective investment. Decisions about police department funding are handled by people different from those who harden levees or fund hospitals [10].

The second new issue concerns how competing corporations that control critical infrastructure should invest in counterterrorism protection. For example, air traffic is critical to the national economy, and it is a shared responsibility among different firms. Each firm needs to decide how much it will invest in security operations. One strategy says that a company should spend just enough to be the second most vulnerable target – that way terrorists will exploit the

most vulnerable and the company has not overspent on protection. Another strategy is to encourage all of one's competitors to invest in security, and claim to do so too, but then to secretly defect, thereby getting a free ride from the expenditures of others. This line of work points up the need for public sector regulation to ensure uniform levels of protection, as has, in fact, happened with airline security [11].

Adversarial Risk

Adversarial risk is an emerging area of risk research that involves game theory (*see Risk Measures and Economic Capital for (Re)insurers; Group Decision; Game Theoretic Methods*). It treats situations in which threats are posed by intelligent opponents, who choose actions nonrandomly to maximize damage to infrastructure. The classic example is terrorism, but the issues also arise in corporate competition and cybersecurity.

In conjunction with game theory, one also needs to use risk analysis. Classical game theory assumes that the costs to attack and defend a particular target are known, but in fact these are often uncertain. Statistical risk analysis supports game theory by determining the joint distribution of the unknown cost matrix used in the game-theoretic formulation.

In many situations, particularly those in which the game involves the possibility of repeated play, it may be also appropriate to consider some optimization procedure, such as dynamic programming (*see Optimal Stopping and Dynamic Programming*), to determine how the opponents allocate their resources for attack and defense to achieve acceptable levels of risk and reward. For example, some terrorist organizations plan multiple attacks staggered over multiple years (though other terrorists, such as Timothy McVeigh, invest in a single, all-or-nothing attack). Similarly, competing corporations rarely bet the firm in an all-out attack; rather they use more cautious strategies that ensure they will still have operating capital and market share in subsequent years of potential competition.

The combination of these three techniques is difficult, and in many applications decision makers use various shortcuts. At the Department of Homeland Security, people often use red-teaming to inform decisions; here one asks a group of smart people with diverse skills to plan attacks as if they were specific groups of terrorists, and then analysts decide

what kinds of target hardening are most protective against threats developed by the red team. Corporate approaches to adversarial risk seem even less formal.

The remainder of this section discusses how the three components of the problem (game theory, risk analysis, and optimization) can be combined. At the same time, we emphasize that in practical applications one must often make gross approximations.

Game Theory

Game theory is a mature field of mathematics; Myerson [12] offers a general overview of the technical aspects. But the main idea, from the standpoint of an infrastructure protection example, is simple. Suppose that terrorists are considering an attempt to bomb a subway station. In broad strokes, they have three options: do not make the attempt, try something cheap and simple, or invest in a major attack. Correspondingly, again in broad strokes, counterterrorists can choose to ignore the threat, or provide inexpensive hardening, or to invest in significant protection.

From a game theory standpoint, this situation can be represented by a cost matrix (see Table 1).

The entries in each cell of the matrix represent the costs for a particular attack/defense combination (this assumes a zero-sum game, which is approximately reasonable in this example, and our convention is that the entries are interpreted as the cost to the defender).

If one knows what the values of the C_{ij} terms are, then there are several approaches to finding the optimal attack strategy and the optimal defense strategy. The classical solution is to use the minimax theorem; here the terrorist looks for the column that maximizes the minimum cost, and the counterterrorist looks for the row that minimizes the maximum cost. If this row and column intersect in the cell that achieves both criteria, then the solution to the game is unique and the best plan for both parties is determined. If not, then a related but more complex

Table 1 Illustration of a payoff table in counterdefense for a normal form two-person zero-sum game with random payoffs

	No attack	Minor attack	Major attack
No defense	C_{11}	C_{12}	C_{13}
Weak defense	C_{21}	C_{22}	C_{23}
Strong defense	C_{31}	C_{32}	C_{33}

“mixed” strategy, based on randomization and the solution of a system of linear equations, is optimal.

There are alternative approaches. A Bayesian version of game theory (*see* **Near-Miss Management: A Participative Approach to Improving System Reliability**) developed by Kadane and Larkey [13] uses a distribution over the actions of one’s opponents to reflect uncertainty about his or her choice. The distribution is subjective, but presumably incorporates minimax calculation, knowledge of psychology, and a truncated “I know that he knows that I know that he knows . . .” kind of argument. Given this subjective distribution, the player chooses the action that minimizes his or her expected loss.

Many people criticize game theory as an unreasonable model for human behavior. In particular, real decision makers often make choices using intuition rather than calculation. Kahneman and Tversky [14] describe many experiments that show that decision makers are often technically irrational, in the sense that they do not select the optimal choices in a particular situation. However, this does not mean that game theory ought not guide real-life solutions, and if one’s opponent makes choices that are suboptimal in terms of game theory, then optimal play on one’s own part is an advantage.

Risk Analysis

Traditional game theory assumes that the entries C_{ij} are known precisely. In fact, for most situations, such as the motivating example of a subway bombing, one has only a vague understanding of the costs.

For example, suppose the terrorists decided upon a weak attack (perhaps something similar to the London Tube bombing on July 7, 2005, undertaken by a small number of amateurs) and the counterterrorists decided upon a weak defense (again, perhaps similar to the routine police surveillance that was in place before the London tube bombing). Then it could happen that the terrorist plot is entirely thwarted, or that the terrorists had to detonate their bomb prematurely and caused minimal damage, or that the terrorists were lucky and the subway was crowded and the damage was devastating. These outcomes are random events whose probabilities can be assessed through classical risk analysis techniques.

To estimate the random costs to Great Britain in this scenario is not easy, but it is susceptible to the kinds of nonadversarial risk analysis techniques

described previously in this article (because we have conditioned on the adversarial component of the problem in fixing the kind of attack and the kind of defense). Components of this analysis would include the following:

- finding the distribution of the number of people at risk by consulting transit ridership data from the previous year;
- assessing probabilities from explosives experts about the likely size of a blast and the number of people who would be killed or injured as a function of the timing and placement of the explosive;
- assessing the probability of preemptive discovery from police records on similar previous attempts, for example, by Sinn Féin or from suicide bombers in Israel;
- consulting with civil engineers to estimate the distribution of the repair cost under different scenarios of destruction;
- consulting with health care economists to determine the medical costs of caring for the injured;
- consulting with social psychologists and market economists to estimate how many people would avoid using the subway, and the financial impact this would have.

This is not an exhaustive list, but it indicates the range of expertise that would be needed and the kinds of data sources that might support the expert judgments.

From these inputs, the risk analyst would develop an equation that represents the random cost as a mathematical function of a number of random variables, where the distribution of each random variable is determined by elicitation of expert opinion or previous data (as with the transit ridership records). Elicitation of expert opinion is not always reliable (*cf.* [5]), but there are no real alternatives when attempting to do risk analysis in situations for which there is little historical data. Fortunately, it is often sufficient to have an equation that is order-of-magnitude correct; the decision that is ultimately obtained from this kind of analysis is often insensitive to minor inaccuracies and approximations. Usually it is more important that the equation be transparent and reasonable than that every single little detail be micromodeled.

To put things on a common footing, it is probably unavoidable to monetize very different quantities, such as the value of a life or the loss in quality of life

associated with fear to travel by subway. Monetizing the value of life is always controversial; some people use expected income or expected productivity, whereas others take account of noneconomic value.

This kind of analysis would be repeated for each cell in the game theory cost matrix. Many of the random variables would be the same from cell to cell (e.g., the transit ridership distribution or the medical cost of treating an injured person) but some (such as the chance of success or the number of bombs planted) might be very different, depending on the attack–defense pair that define the cell.

The risk analyst views the cost matrix as a random matrix with the joint distribution of the entries determined by the mathematical functions of the random variables involved in estimating the component costs. This enables the analyst to use repeated sampling to determine the probability that a particular defense is the one that minimizes the cost. Specifically, the analyst draws many realizations of the random cost matrix, and for each matrix determines the game-theoretic solution (either by applying the minimax criterion, or the minimum expected loss criterion from the Kadane–Larkey approach, or by some other procedure). Thus the analyst can estimate the proportion of matrices for which a particular choice of defense is optimal, and advise decision makers accordingly. (See [15], for a detailed example in the context of the decision about whether to inoculate the general US population against smallpox.)

For some applications, it can happen that the outcome is very sensitive to the assumptions made in the risk analysis or the game-theoretic solution technique that is chosen. However, often there is little sensitivity, typically because a few cells with large costs dominate the decision. Additionally, this methodology allows decision makers to explore “what-if” scenarios, to see how changes in assumptions or resourcing affect the outcome.

Portfolio Analysis

The preceding analysis of adversarial risk is incomplete because it does not capture resource constraints on the adversaries and long-range planning objectives that shape their investments in attacks and defenses. The branch of mathematics that addresses these elements is *portfolio theory*.

It is reasonable to imagine that some kinds of terrorists expect to operate for the foreseeable future. They would need be unlikely to sink all their resources into a single attack, and they would want to stage their different attacks so as to ensure a steady record of high-profile successes, in order to encourage recruitment and donations. On the other hand, different kinds of terrorists might gamble all their resources on one effort (if history is a guide, these tend to be small groups of amateurs). And, from the standpoint of the counterterrorists, nations cannot bankrupt their future to purchase a defense, and they will want to spread security investments among different programs so as to maximize the net protection. (The same issues apply to corporate competition; businesses need to plan their attacks and defenses within fixed budgets and with long-term planning horizons.)

From this perspective, one can describe the problem in terms of investment in a portfolio (*see Role of Alternative Assets in Portfolio Construction; Risk in Credit Granting and Lending Decisions: Credit Scoring*) of attacks (or defenses). A terrorist decision maker must allocate a certain amount of money, time and people among truck bombs, nuclear devices, biological pathogens, and so forth; similarly, the counterterrorists can spread their investments among border security, airline passenger screening, intelligence operations, cargo inspection, and so forth. And, as the game is played repeatedly over time, some of these investments may be redirected, just as one can reshuffle money among one’s stock market portfolio, or buy new stocks.

Portfolio analysis is hard and relies upon dynamic programming. The goal is to maximize return under constraints on the amount of risk one is willing to accept. As one observes market history, one adaptively changes the portfolio to best achieve one’s goals in a stochastic environment. The analogy to the decisions of terrorists and counterterrorists, or competing firms, is immediate.

Currently, no formal portfolio analysis has been undertaken in the context of infrastructure protection. But informal analyses appear in many places; the United States has made decisions about which kinds of defenses will be supported, and the amount of risk it is willing to tolerate. Nonetheless, one imagines that a rigorous analysis might find more cost-effective investments.

Public Health Surveillance

Public health surveillance (see **Environmental Exposure Monitoring; Digital Governance, Hotspot Detection, and Homeland Security**) has been described as the “ongoing, systematic collection, analysis, and interpretation of health-related data essential to the planning, implementation, and evaluation of public health practice, closely integrated with the timely dissemination of these data to those responsible for prevention and control” [1]. Recently, terms such as *syndromic surveillance* (see **Syndromic Surveillance**), *biological surveillance*, and *biosurveillance* (see **Sampling and Inspection for Monitoring Threats to Homeland Security**) have been coined to describe somewhat more time-sensitive versions of public health surveillance.

The broad topic of public health surveillance includes two very different activities. *Case surveillance* (see **Dynamic Financial Analysis**) focuses on individuals, or sometimes groups of individuals, to identify individuals with certain diseases and take action to stop spread of disease. *Statistical surveillance* (see **Managing Infrastructure Reliability, Safety, and Security**), on the other hand, focuses on populations to identify differentials and trends that can inform public health policymaking, including the allocation of resources. Both approaches have roots going back at least into the nineteenth century and beyond, but it was not until 1963 that Alexander Langmuir of Centers for Disease Control and Prevention CDC combined them in his classic definition of public health surveillance [2], which formed the basis for that quoted above. Case surveillance and statistical surveillance, however, involve different goals and objectives, data sources, and methods. Indeed, the contrast between them seems responsible for some of the current controversies about modern biological and syndromic surveillance, which sits uncomfortably in both worlds.

This paper begins by identifying the goals and summarizing the history of public health surveillance, and describes some of the key data sources used. This is followed by a discussion of recent developments in biological and syndromic surveillance from a public health perspective. Many of the examples are from the United States, but the situation is similar in other countries.

The Goals and History of Public Health Surveillance

Surveillance is regarded as an essential public health service and is part of the “assessment” function of public health. The Institute of Medicine defined assessment as collecting, assembling, analyzing, and making information available on the health status and health needs of the community [3]. Traditional public health surveillance, a critical part of the assessment function, seeks to assess and track the health of the public, define public health priorities, evaluate programs, and stimulate research [4]. CDC also lists a number of “uses” of surveillance: estimating the magnitude of a health problem, determining the geographic distribution of illness, portraying the natural history of a disease, detecting epidemics, generating hypotheses, stimulating research, evaluating control measures, monitoring changes in infectious agents, monitoring emerging and reemerging infections with laboratory data, detecting changes in health practices, and facilitating planning [4].

The first use of public health surveillance was in the Republic of Venice in the fourteenth century. At that time, public health authorities boarded ships to identify persons with symptoms of bubonic plague and to prevent them from disembarking. In 1741, Rhode Island required tavern keepers to report patrons with smallpox, yellow fever, and cholera to local authorities. Statewide efforts began in Massachusetts in 1874. At that time, a voluntary, post-card reporting format was used to provide weekly reports on prevalent diseases. In 1878, Congress authorized the forerunner of the United States Public Health Service (PHS) to collect morbidity data for use in quarantine measures against “pestilential diseases” such as cholera, smallpox, plague, and yellow fever [5]. Compulsory reporting of infectious diseases began on a national basis in Italy in 1881, and in other European countries shortly afterwards. At the global level, the World Health Organization (WHO) (see **Polychlorinated Biphenyls; Cohort Studies**) modified the International Health Regulations in 2005 to require that all countries notify WHO of all events “that may constitute public health emergencies of international concern”. This requires that countries have the core surveillance and response capacities needed to fulfill the international reporting requirements [6].

From the start, surveillance was focused on detecting individual cases and taking action regarding the affected individuals. Control strategies include monitoring, treatment, quarantine, and contact tracing. Indeed, smallpox was eradicated in the 1970s using a surveillance-based approach. Earlier efforts to immunize nearly 100% of the population failed because of logistical difficulties. The successful “ring strategy” relied on intensive surveillance for identification of cases, isolation of all known cases, and immunization of individuals who may have come in contact with cases [7].

There are few cases these days of “pestilential diseases” for which immediate action is necessary, but the need for quick action to prevent the spread of infectious diseases does remain. For tuberculosis and sexually transmitted diseases, for instance, one of the main goals of surveillance is to identify infectious individuals before they infect others and thus to prevent an exponentially growing epidemic. Case surveillance has received additional prominence along with the increasing interest in emerging infections and, since 9/11, in bioterrorism. Enhancing health departments’ ability to receive and respond effectively to case reports is a critical component of the efforts of public health preparedness [8].

Surveillance also has a history as a statistical activity, although the term “surveillance” was not applied until the mid-twentieth century. In this perspective, surveillance focuses on populations rather than on individuals. The earliest statistical surveillance activities made use of vital statistics, primarily derived from death certificates. The analysis of vital statistics began with von Leibnitz and Graunt in the seventeenth century and was extended to examine cause of death and applied to public health in the nineteenth century by Farr in England and Shattuck in the United States [5].

Statistical surveillance also includes health surveys based on scientifically chosen sample surveys. The first national health survey was conducted in the United States in 1935, and the National Health Interview Survey (NHIS) has been in continuous operation since 1957 [9]. In the 1990s, the CDC developed the behavioral risk factor surveillance system (BRFSS), a model for state population health surveys, which is now used by all states and the District of Columbia [10]. In addition, many special-purpose surveys are now available and commonly used.

Registries are another source of data for statistical surveillance. The National Cancer Institute (NCI) surveillance, epidemiology, and end results (SEER) system, which operates in 11 population-based cancer registries and 3 supplemental registries covering approximately 14% of the US population, uses active surveillance methods to record all incident cases of cancer as well as their treatments and outcomes. As a result, NCI is able to estimate cancer incidence and survival rates (*see Risk Classification/Life; Reliability Data; Lifetime Models and Risk Assessment*), such estimation not being possible for most chronic diseases [11].

The extension of the original focus of surveillance from infectious diseases to other aspects of public health paralleled developments in our understanding of the determinants of health and of public health itself. The original focus in vital statistics on all-cause mortality in the seventeenth century expanded to cause-specific mortality in the nineteenth century as more became known about the causes of disease [12]. In the second half of the twentieth century, public health and surveillance began to focus on chronic diseases, and simultaneously on health risk factors as well as on health care utilization, costs, outcomes, and so on. In 1979, *Healthy People* created awareness community health indicators, performance measures, and so on [13], and surveillance efforts of this type have increased with publication of *Healthy People 2000* and *Healthy People 2010* [14, 15]. Etches and colleagues review similar efforts in Canada and other countries and suggest a framework for using indicators to report on all the domains of population health [16].

Surveillance of occupational morbidity and mortality, developed in concert with new regulations on workplace safety regulation, and surveillance of injury became more common in the 1990s as public health turned its attention to intentional and unintentional violence. A growing focus on health care quality in the early twenty first century and attendant concerns about medical errors and iatrogenic injuries in recent years [17, 18], have led to intensified surveillance efforts, along with postmarketing surveillance for adverse effects of drugs and vaccines [19].

Surveillance Data

In order to support the different purposes and uses summarized above, surveillance systems rely

on a diversity of data sources. Infectious disease surveillance, for instance, still relies primarily on the system of notifiable diseases put in place in the nineteenth century. Health care providers are required to report all cases of a given set of diseases to their local health department. Reports are generally made by name and with a variety of information relating to possible risk factors to the local health department in which the patient resides. Local health departments report to state health departments, usually by mail, and states compile reports and transmit them to the CDC for national tabulation and publication. Disease surveillance systems have generally been developed for specific diseases and differ from one another in what information is requested, how it is reported, and so on.

Not surprisingly, given this fragmented system and the demands of the modern health care system, physicians' compliance with this *passive surveillance* system is limited. Moreover, some individuals may not experience symptoms or have good access to health care, and thus do not seek care. As a result, health officials acknowledge that the number of reported cases of a disease can be far below the number of actual cases. In addition, because most surveillance systems require laboratory confirmation of a diagnosis before it is reported, there can be substantial delays between the development of symptoms in an individual and reporting to health officials.

Two recent developments may help to improve the completeness and accuracy of case reports. First, health departments are developing systems for clinical laboratories to report cases that test positive directly to state or local health departments rather than through physicians. While this may make reporting both more complete and timely, laboratories generally do not have all the clinical and demographic information on the cases that is necessary. Moreover, managed care organizations and other organized health care delivery systems are increasingly using out-of-state laboratories, and linking the information back to the proper local health department can be difficult. Second, CDC is developing a National Electronic Disease Surveillance System (NEDSS) for transmitting surveillance information electronically but it has only been implemented in a few states [20]. Current implementations, however, are focused on communication between local and state agencies and with the CDC, and direct links to providers are not generally available. With the

increased emphasis on surveillance after September 11, linkages to physicians, hospitals, and laboratories are being developed [20].

Vital records, based on individual birth and death certificates, are another important source of surveillance data. Unlike disease case reports, however, birth and death certificates are legal documents that are essential to the persons concerned and their families, and thus there is a strong incentive for the reports to be complete. Timeliness has generally not been an issue with vital statistics and the emphasis has been on completeness and accuracy in their compilation and analysis.

Registries for cancer and other diseases, as described above, provide data on disease incidence, treatments, case fatality, and health outcomes. They generally rely on *active surveillance* efforts, where registry personnel regularly contact physicians, hospitals, and other health care providers to ascertain new cases and learn about developments on existing cases. Because of the cost of these efforts, registries only exist for selected diseases and in limited geographic areas. As with vital records, registry data tend to be analyzed and reported in statistical terms, and the focus is on completeness and accuracy rather than timeliness.

Sentinel surveillance efforts are specially focused, intensive efforts to identify disease incidence and case characteristics in special settings. Because influenza case surveillance reports are very incomplete, for instance, CDC has organized the Sentinel Provider Network (SPN), which consists of approximately 1200 healthcare providers nationwide, who report the number of weekly outpatient visits for influenza-like illness (ILI) [21].

Population-based surveys using scientifically selected random samples provide useful data for statistical surveillance activities. The NHIS and BRFSS, as discussed above, are general-purpose surveys at the national and state levels, respectively, and many other special-purpose surveys have been developed and used at the national, state, and local levels, and for special populations. Population-based surveys are designed to make estimates of the total number of cases using statistical techniques, but not to identify all cases of a particular disease or health condition. The accuracy of these estimates depends on the selection of the sample, complete and accurate reporting by those in the sample, and use of proper statistical methods to analyze the data. Because the

individuals providing data are only a sample of the target population, attempts are generally not made to respond to cases that are identified in the survey.

The final major source of surveillance data is medical records and administrative systems. Such records have existed for many years, but they are increasingly used for both research and surveillance purposes now that they are available in computerized form. Because medical decisions and payments are based on such documents, they are generally regarded as nearly complete. Their administrative and clinical use, however, can introduce biases. An individual's condition, for instance, may be "upcoded" to increase a hospital's or a physician's reimbursement. Such records may also not include information such as risk factors or race and socioeconomic status, which can be useful for surveillance purposes. New federal regulations established in response to the Health Insurance Portability and Accountability Act (HIPAA) restrict the use of patient information to protect privacy and confidentiality. Hospitals and physicians can, however, disclose protected health information for public health activities authorized by law [22].

Syndromic Surveillance

Heightened awareness of the risks of bioterrorism since 9/11, coupled with a growing concern about naturally emerging and re-emerging diseases such as West Nile, severe acute respiratory syndrome (SARS), and pandemic influenza have led public health policymakers to realize the need for early warning systems and, more generally, improved surveillance. The sooner health officials know about an attack or a natural disease outbreak, for instance, the sooner they can treat those who have already been exposed to the pathogen to minimize the health consequences, vaccinate some or all of the population to prevent further infection, and identify and isolate cases to prevent further transmission. In addition, it is felt that improved surveillance systems should allow for better "situational awareness" and thus help to manage the response to public health emergencies.

Traditional public health surveillance approaches monitor disease using prespecified case definitions and use manual data collection, human decision-making, and manual data entry. In contrast, current electronic biosurveillance systems use sophisticated information technology and statistical methods to

gather, process, and analyze large amounts of data and display the information for decision makers in a timely way. For instance, syndromic surveillance systems assume that during an attack or a disease outbreak people first develop symptoms, then stay home from work or school, attempt to self-treat with over-the-counter (OTC) products, and eventually see a physician with nonspecific symptoms days before they are formally diagnosed and reported to the health department. To identify such behaviors, syndromic surveillance systems regularly monitor existing data for sudden changes or anomalies that might signal a disease outbreak. Syndromic surveillance systems have been developed to include data on school and work absenteeism, sales of OTC products, calls to nurse hotlines, and counts of hospital emergency room (ER) admissions, or reports from primary physicians for certain symptoms or complaints [23]. Fricker offers a more detailed discussion on the various statistical methods and algorithms used in syndromic surveillance.

CDC's system for electronic biosurveillance, BioSense, was initiated in 2003 and currently receives data from national healthcare organizations including the Department of Defense (DoD), Veterans' Affairs (VA), and other sources. The ICD-9 diagnosis codes and current procedural terminology (CPT) procedure codes from these sources are binned into 11 syndromes. Data analyses are displayed in the BioSense application, which can be viewed through the CDC secure data network by CDC, state and local health departments, and DoD and VA personnel [24]. In mid-2005, CDC began to develop the capacity, through BioSenseRT, to receive real-time data from hospital facilities across the United States. This initiative emphasizes access to real-time clinically rich data. Individual patient records are stripped of obvious identifiers such as names, addresses, and telephone numbers at the data source before being sent to CDC. Patient populations include those treated in the emergency department (ED), hospital inpatient, and hospital-affiliated outpatient settings. Hospital-level data includes the daily hospital census. Patient-level data of interest includes patient's chief complaint, physician diagnosis, selected ED-specific data (e.g., vital signs), microbiology laboratory orders and results, radiology order and results, and pharmacy orders. As of December 2005, chief complaint, diagnosis, and selected demographic data were being received from 32 hospitals in 10 cities

distributed across the United States; and plans call for the number of hospitals to increase to 350 [25]. BioSense's vision is to (a) provide local, state, and nationwide health situational awareness for suspected illness and cases of disease before, during, and after a health event; (b) help confirm or refute the existence of an event; and (c) monitor the size, location, and rate of spread of disease outbreaks [26].

Recognizing that the "ability to gather and analyze information quickly and accurately would improve the nation's ability to recognize natural disease outbreaks, track emerging infections, identify intentional biological attacks, and monitor disease trends," the Institute of Medicine has recently called for more research on syndromic surveillance and other "innovative systems of surveillance that capitalize on advances in information technology". However, since surveillance systems in the United States "remain fragmented and have not evolved at the same rate as ... electronic technological advances," the Institute of Medicine calls for these systems to be "carefully evaluated for their usefulness in detection of infectious disease epidemics, including their potential for detection of major biothreat agents, their ability to monitor the spread of epidemics, and their cost effectiveness" before widespread implementation [27].

Practical Concerns about Syndromic Surveillance in Public Health Practice

Despite the generally recognized promise of syndromic surveillance and other electronic biosurveillance systems, there are practical concerns about the use of these systems, and BioSense in particular, in state and local public health practice.

Reingold provocatively noted the challenges confronting syndromic surveillance: characterizing the types of bioterrorist events that it is likely to detect, determining whether it can help identify the population at risk in a more timely way during a bioterrorist event, determining the appropriate response to apparent increases in illnesses signaled by syndromic surveillance, and ultimately demonstrating that it can reduce morbidity and/or mortality following a bioterrorist event. Reingold also notes the likelihood that syndromic surveillance will produce useful information about naturally occurring diseases and the importance of identifying the circumstances under which it is likely to strengthen local and state public health departments [28].

The possibility of earlier detection and more rapid response to a bioterrorist event has tremendous intuitive appeal, but its success depends on local health departments' ability to respond effectively. When a syndromic surveillance system sounds an alarm, health departments typically wait a day or two to see if the number of cases continues to remain high or if a similar signal is found in other data sources. Doing so, of course, reduces both the timeliness and sensitivity of the original system. If the health department decides that an epidemiological investigation is warranted, it may begin by identifying those who are ill and talking to their physicians. If this does not resolve the matter, additional tests must be ordered and clinical specimens gathered for laboratory analysis. Health departments might also choose to initiate active surveillance by contacting physicians to see if they have seen similar cases.

Additionally, a syndromic surveillance system that only says "there have been five excess cases of flu-like illness at hospital X" is not of much use unless the five cases can be identified and reported to health officials. For example, if there are 55 rather than 50 cases expected, syndromic surveillance systems cannot say which 5 are the "excess" ones, and all 55 must be investigated. Health departments cannot act simply on the basis of a suspicion. Even when the cause and route of exposure are known, the available control strategies – quarantine of suspected cases, mass vaccination, and so on – are expensive and controversial, and often their efficacy is unknown. Coupled with the confusion that is likely during a terrorist attack or even a natural disease outbreak, making decisions could take days to weeks.

Syndromic surveillance systems are intended to raise an alarm, and all alarm systems have intrinsic statistical trade-offs. The most well known is between sensitivity, the ability to detect an attack when it occurs, and the false-positive rate, the probability of sounding an alarm when there is in fact no attack. The costs of excessive false alarms are both monetary, in terms of resources needed to respond to phantom events, and operational, as too many false events desensitize responders to real events. Taking into account the different data types and multiple jurisdictions, thousands of syndromic surveillance systems soon will be running simultaneously in cities and counties throughout the United States. If 1000 data streams are being monitored, each with a 0.1%

false-positive rate (which is very low), there will be approximately one false alarm per day.

The timeliness of a surveillance system depends on the time it takes to generate and acquire data, analyze it, and take action [29]. With syndromic surveillance, an additional component is the time that it takes to accumulate enough evidence of an outbreak to trigger a detection algorithm. To illustrate this point, Stoto and colleagues used a simulation approach to analyze ILI-related ER admissions data from a typical urban hospital. A hypothetical number of extra cases spread over a number of days were added to actual baseline data to mimic the pattern of a potential bioterror attack (*see Digital Governance, Hotspot Detection, and Homeland Security*). The results indicate the size and speed that outbreaks must attain before they are detectable. These results are sobering: even with an excess of 9 cases over 2 days (the first 2 days of the “fast” outbreak), three times the daily average, there was only about a 50% chance that the alarm would go off. When 18 cases were spread over 9 days, chances were still no better than 50–50 that the alarm would sound by the ninth day. Moreover, this finding holds true only outside of the winter flu season. In the winter, the detection threshold (*see Hazardous Waste Site(s); Early Warning Systems (EWSs) for Predicting Financial Crisis*) must be set high so that the flu itself does not sound an alarm, but a terrorist attack that appeared with flulike symptoms would be harder to detect (Figure 1) [30]. Fricker and Rolka discuss other statistical challenges to the development and effective use of electronic surveillance systems in public health practice [31].

Ultimately, the value of syndromic surveillance as an early detection system depends on how well it is integrated into public health systems. The detection of a sudden increase in cases of flulike illness – the kind of event that syndromic surveillance can detect – can have varied significance. It could be a bioterrorist attack but is more likely a natural occurrence, perhaps even the beginning of the annual flu season. An increase in sales of flu medication might simply mean that pharmacies are having a promotion. A surge in absenteeism could reflect natural causes, or even a period of particularly pleasant spring weather. Similar problems can occur even with the more complete dataset in the real-time implementation of BioSenseRT. For example, changes in local hospital systems, or even in coding practices, can result in

Figure 1 Sensitivity of syndromic surveillance (probability of detection by day) for influenza-like illness at a typical urban hospital emergency room using four detection algorithms, (a) fast outbreak: 18 cases over 3 days, (b) slow outbreak: 18 extra cases over 9 days [Reproduced from [30] © Springer New York LLC, 2004.]

substantial changes that could raise concern if they are not understood.

Alternative Applications of Syndromic Surveillance

Since 9/11, the focus of syndromic surveillance efforts has been on early detection of bioterrorist events. The most value, however, may ultimately come from its use in the detection of natural disease outbreaks. More generally, if twenty-first century bio-surveillance means effective use of health information technology in identifying cases before they are formally diagnosed, it can supplement traditional public health approaches and improve their effectiveness.

One potential use is in detecting influenza outbreaks. In an “ordinary” year, influenza results in approximately 36 000 deaths and more than 200 000 hospitalizations in the United States. In addition to

this human toll, influenza is annually responsible for a total cost of over \$10 billion in the United States. A pandemic, or worldwide outbreak of a new influenza virus, perhaps evolving from the H5N1 avian flu virus circulating in Asia, could dwarf this impact by overwhelming our health and medical capabilities, potentially resulting in hundreds of thousands of deaths, millions of hospitalizations, and direct and indirect costs of hundreds of billions of dollars [32]. Electronic biosurveillance systems, syndromic surveillance, and BioSense feature prominently in federal, state, and local plans to prepare the United States for pandemic flu.

CDC has a number of influenza surveillance systems in place [21], yet they do not provide population-based rates of incidence or prevalence rates on a national level because many infected persons are asymptomatic or experience only mild illness and do not seek medical care. Also, laboratory testing is rare in less severe cases, and testing occurs late in the course of illness (e.g., in cases with severe complications) and can yield false-negative results because the patient is no longer shedding virus.

Epidemiological characteristics (*see Molecular Markers and Models; Meta-Analysis in Nonclinical Risk Assessment*) of both seasonal and pandemic influenza, however, suggest that syndromic surveillance and other biosurveillance systems are likely to make an important contribution beyond the capabilities of existing surveillance systems, and thus enable a more effective public health response [33]. Simulation studies have shown that unless a bioterrorism outlook is exceptionally large, syndromic surveillance detection algorithms take on the order of days to detect them [30, 33, 34]. This time frame is longer than some proponents of syndromic surveillance feel is needed to detect bioterrorism [35]. Compared to the current influenza surveillance systems, however, a 1-week lead time would provide valuable information, and this is likely to be achievable for syndromic surveillance.

Furthermore, a number of studies have demonstrated the potential that syndromic surveillance of ILI offers at the national, state, and local level. Sebastiani and colleagues show that children and infants presenting to the pediatric ED with respiratory syndromes are an early indicator of impending influenza morbidity and mortality, sometimes by as much as 3 weeks [36]. Using data from New York

City, Lu and colleagues have shown that monitoring both outpatient and ED data can enhance detection of ILI outbreaks [37]. With similar data, Olson and colleagues note that age-stratified analyses of ED visits for fever and respiratory complaints offers the potential for more precise quantification of the burden of illness, earlier warning of the arrival of epidemic influenza, and greater sensitivity for detecting the characteristic age shift of pandemic influenza [38]. Comparing unspecified infection cases in DC hospitals using optimal detection algorithms to CDC's sentinel physician data for the South Atlantic states for 4 years in which there was a discernable influenza outbreak, Stoto and colleagues found that in two of these years, the DC syndromic surveillance based on hospital ER data outperformed the other two systems, and in 1 year it flagged only 2 days after the CDC system [39]. Given a built-in delay of about 2 weeks in the CDC system, this is a substantial advantage.

Even in normal flu seasons, laboratory analysis to determine whether a case is truly influenza, or to identify the viral strain, is rarely done. Pandemic influenza, in which an antigenic shift causes an outbreak that could be more contagious and/or more virulent and to which few people are immune by virtue of previous exposure, is a growing concern. Syndromic surveillance of flulike symptoms might trigger more laboratory analysis than is typically done, and in this way hasten the public health response. In a normal flu season, Labus has reported that early identification of the start of the influenza season using syndromic surveillance in Clark County Nevada enabled the notification of the medical community. Physicians were encouraged to submit specimens for culture, and the county health department provided kits to help them do this, which allowed for rapid identification of the major circulating strain. In 2003–2004 (a period with a marked increase of early season influenza and deaths in children in other parts of the country), this syndromic surveillance system allowed for better tracking, and provided data for daily reports to decision makers and the media [40].

Because of their focus on the early detection of bioterrorist events, syndromic surveillance systems are intended to detect large increases in the number of people with common symptoms such as ILI. As such, they cannot be expected to detect small numbers of cases, even if very unusual. One reason is that in a small disease outbreak or the early stages of a larger

one, each case will be seen by only one physician. The natural tendency of physicians who see only one case, however suspicious it may be, is to discount it. After all, physicians are appropriately taught “when you hear hoofbeats, think horse not zebra”. And some may fear the embarrassment of reporting a case that may turn out to be a false alarm.

Modern health informatics systems provide the potential to identify the presence of small numbers of cases of concern before they are formally diagnosed. Automated systems can, for instance, aggregate data for a metropolitan area spanning local reporting jurisdictions to identify, say, cases of rash and fever, which would suggest smallpox. Systems can also be set up to enable and encourage early reporting of cases on the basis of symptoms only. For instance, the syndrome reporting information system (SYRIS), now operating in Lubbock Texas and elsewhere, enables physicians to report suspicious cases to the local health department without waiting for laboratory confirmation, and encourages them to do so by providing feedback in the form of information about practice guidelines and other similar cases [41]. This can be thought of as a kind of active syndromic surveillance or as IT support for astute physicians.

Real-time access to prediagnostic data can also help health authorities respond to public health threats. If person-to-person transmission of avian flu virus is documented in Asia, for instance, health department in Europe and the United States might want to identify and follow-up on local cases of people hospitalized with flulike symptoms, and syndromic surveillance systems could be designed to identify them. If an environmental sensor detects signs of possible terrorist agent tularemia, syndromic surveillance systems can be checked for cases with appropriate symptoms. This actually occurred in Washington DC in 2005, and the lack of cases in area ERs reassured local officials that the alarm was false. Syndromic surveillance systems can also be queried to determine background rates when it is not clear whether a reported cluster of cases is out of the ordinary.

The *Escherichia coli* O157:H57 outbreak in the New York City area in late 2006 provides an example of how syndromic surveillance could have been used for case finding. The outbreak came to light on November 17 when the first case was reported to a local health department in New Jersey. By November 27, 11 cases were reported in that jurisdiction and

3 days later the Taco Bell restaurant, where 9 of the 11 cases had eaten, closed voluntarily. On December 1, a similar case (originally attributed to another cause) was reported to a local health department in New York State, and it turned out that this person and three more cases in that jurisdiction had eaten at a different Taco Bell restaurant. By December 4, all Taco Bells in the New York metropolitan area were closed, and 2 days later a particular food item, green onions, was identified as the likely source of contamination. By December 9, more than 61 *E. coli* O157:H57 cases in at least four states were reported [42].

Although a number of syndromic surveillance systems were operating at this time in New York City and the surrounding jurisdictions, there were too few cases in any location to detect. However, once the outbreak was identified in New Jersey, an advanced syndromic surveillance system could have searched ED admissions for cases of bloody diarrhea and abdominal cramps in the entire metropolitan area. Cases so identified could have been interviewed to obtain a food history and lab samples could have been obtained to test for *E. coli* O157:H57. In addition, health departments could have initiated active surveillance by physicians in the area, searched data from surrounding states to identify additional cases for follow-up and to confirm lack of cases elsewhere. If these things had been done, it is possible that the restaurant chain and green onions could have been identified and remedial steps taken earlier – either closing the restaurant or removing the green onions. It is also likely that the additional data that syndromic surveillance systems with these capabilities could have provided would have generated information to resolve the uncertainty about what was happening, and thus diminish public concerns.

Conclusions

Disease surveillance, combining case-finding efforts with statistical approaches to track population health trends, is an essential core function of public health. In some respects, however, its methods have changed little since the nineteenth century. The introduction and growth of syndromic surveillance following 9/11 has focused on a statistical approach to detecting bioterrorist attacks, and much impressive research and development has been done with respect to the real-time integration of many disparate data streams

and other aspects of information technology, and to the development of statistical detection algorithms. Despite these accomplishments, the value of syndromic surveillance for detecting bioterrorist attacks has not yet been demonstrated. This is because of the relatively narrow window between what can be detected in the first few days and what is obvious, and the need for better integration with public health systems.

Ultimately, the most important public health contribution of syndromic surveillance systems may be for natural disease outbreaks, such as seasonal and pandemic influenza, and for other public health purposes beyond simple detection. For this to be achieved, however, syndromic surveillance system designers will have to change their focus from statistical systems and from data appropriate for early detection of large-scale events, and develop tools for public health uses other than outbreak detection.

Public Participation

Public participation processes and stakeholder involvement strategies are adopted to engage people in a decision-making process that they have an interest in, or that may affect them in some way. They may be experts, representatives of different interest groups, or the general public (*see* **Expert Judgment; Group Decision**). Involving different stakeholder groups gives decision makers a clear idea of what the public wants, and involving local people in local decisions may also provide information that may have otherwise been overlooked. By these means, the decision-making process is strengthened and the quality of decision is improved. Participation of different groups with opposing views also helps to resolve conflict. Compromise may be reached with negotiation, and when different viewpoints and values are heard, participants may become more sympathetic to the opposing cause. By opening up the decision-making process to the public, granting them some control over their own environment, and so increasing transparency, trust can be built. Participatory processes also seek to educate and inform the public about matters they may otherwise have been fearful of. Thus, participation processes can be adopted to involve stakeholders in the management of risk and the development of risk mitigation strategies.

Objectives of Participation

There are a number of objectives one may wish to achieve when involving the public in a participatory process. Here the objectives of public participatory processes that have been identified from an extensive literature search are described. Figure 1 gives an overview of the possible objectives of participation. Alongside and leading the practical developments, there have been many academic studies covering issues such as the philosophical underpinnings, categorization of different types of activity, and case studies [1–25]. Beyond the literature on participation and deliberative democracy, there is also other relevant material on discussions of public engagement with science and more generally risk communication [26–31]. Aside from a social science literature, there is also relevant material in the management literature [32–37]. Information systems approaches to

participatory design are also very relevant [38]. In the following sections the objectives of participation are discussed.

Information Sharing

A vital purpose of public participation processes is the exchange of information in order to inform participants and explore issues thoroughly. Scientific and technical information communicated should be made easier to understand, but not oversimplified. Information sharing can be one-way or two-way between stakeholders and authorities and/or decision makers. One-way information sharing from the authority to stakeholders may relate to an event, or be educational to explain “science” and “expert views”, for example, an education campaign highlighting the dangers of drink driving or information dissemination in the event of environmental flooding. Conversely, an authority may seek local knowledge about an issue or an area where complete information is not available. Authorities may wish to determine public perceptions of an issue or understand lay views. Consideration of the way in which the public perceives risks and other information is important to any communication or involvement process. It is well understood in risk perception literature that “lay” judgments and “expert” opinions on the nature of various risks and the hazards they pose differ to a large extent. Neither is necessarily right or wrong but the differences need to be appreciated. It may be feasible to change public perceptions and viewpoints with information provision and, with reassurance, the public are more likely to accept a decision it perceives to involve a high degree of risk. The 1998 Aarhus convention, ratified by 40, Asian and European countries, recognizes that the public have a right to participate in environmental decision making. Incorporation of public values and preferences is an important aspect of public participation processes; the process will have more credibility if the public feel they are being listened to; the decision will be more widely accepted if the public view has been taken into consideration; and the quality of decisions will be improved. Different stakeholders and members of the public hold different values and so it is important to involve a diverse array of people in the process. A two-way information sharing consultation process may be employed for a decision-making

Figure 1 Objectives of participation

process related to a local environment that meet the needs of all stakeholders.

Decision/Risk-Management Quality

More creative alternatives, better identification of risks, and problem formulation can all be achieved by drawing in public and stakeholder ideas early in the process. The success of a public participation process may be determined by the active involvement of participants and their responsiveness to information they have received. In one study [9] of the quality of stakeholder-based decisions, one of the criteria examined was whether participants contributed innovative ideas, useful analysis, or new information. In the majority of cases it was found that the processes did meet this criterion, therefore improving decision quality. The public can provide valuable information and an alternative insight into the decision problem.

Decision quality may be improved by introducing more flexibility in problem formulation and broader framing of issues; in order for the public to understand the decision situation fully, the processes should be adaptable enough to allow participants to raise issues outside the remit of the dialogue process – the process should not predetermine the way in which the decision is discussed [39]. Participants may also widen the framing of a problem by introducing social and ethical issues alongside scientific

and technical ones. The openness of problem framing may be constrained by the process, which may jeopardize the benefits of dialogue. Decision quality may be improved by testing assumptions. As a starting point to any process, assumptions are made in order to guide the process and to be prepared for any information that may surface in discussion, particularly information that may be sensitive. These assumptions should not be constraining and can be tested.

Community Cohesion

A well-designed participatory process may contribute to social cohesion, it can smooth tensions between those closely involved in the issues and who may have conflicting objectives, and it can create a more general feeling of community involvement. Trust is an essential part of any process; if there is no trust then people will become suspicious of the process and of the people involved. Trust is important to break down communication barriers and promote open and honest discussion rather than discussion that is defensive and self-interested. It is particularly important to build and maintain trust between different stakeholder groups and the authority. The decline of public trust in government and government-related institutions in the management of risk situations has been apparent in recent years, especially since public relations disasters such as the BSE crisis in the United Kingdom

where information about this disease in cattle and links between the human form, vCJD, were undisclosed. The decline of public trust in government can be attributed to a number of factors; in particular, public expectations have risen over time – people expect more from organizations and the individuals representing them. Also, there has been a decline in deference to authority so that people are less willing to accept government or “expert” advice without question [40]. Opening up the decision-making process to the public and granting them some control over their own environment aim to increase transparency and build trust. It is important to build trust between different stakeholder groups. Improving trust and understanding between participants can help to encourage more thorough and in-depth discussion.

Democratic Ideals

There are a whole range of democratic issues that need to be considered when designing a participatory process: *Transparency*, to build trust in the authorities conducting the process and in the process itself. Transparency is essential not only for participants but also for the wider public in order for them to accept the decision or the outcome deliberation; the *legitimacy* of the process is important: the reasons for the process, its purpose, and the motivation of the body conducting the process need to be made clear as otherwise participants may feel skeptical and disillusioned with the process; *equality and fairness*, the rights of individuals to participate and express their views fairly and equally; *representativeness* of all stakeholders: to ensure that all viewpoints are represented; and *accountability*, to ensure that decision makers are acting in the public's best interest. However, there may be occasions where participatory processes are not intended to be democratic, for example, the handling of incidents may require too much urgency to debate issues with the public and involve them in the ultimate decisions. Participation in such cases is much more like to be focused on explaining what is being done and why, and perhaps gathering information on the full scale of the likely consequences.

Practicability

Full participation can be very costly and time consuming, requiring complex logistics. The practicalities of participation need to be considered, such as

the costs to hold a consultation process, the demands on resources and on participants' time, and whether the chosen process will produce acceptable outcomes given the constraints.

Characteristics of Different Participatory Processes

The characteristics of the participatory process chosen will reflect the aims and objectives of the task in hand. The number and composition of different stakeholders as participants in a decision-making process may affect the outcome. Different groupings exhibit altered behavior, and group members interact differently depending on the dynamics of the group. Some of the characteristics to consider when designing a participatory process are covered here.

Participants

The participants involved in the process are crucial to its outcome. The way in which participants interact with one another cannot be easily predicted, as different characters bring unique values and insight to the discussion. While participants should be representative of the population affected by the decision, considering qualities such as age, sex, and cultural background may add to the difficulty of the process. There are several ways in which participants may be recruited into the process. Some, such as public hearings, are open to all members of the public. They are publicized and interested parties are invited to attend. In other processes, such as consensus conferences and citizen advisory committees, participants are carefully selected to represent the population concerned. The number of participants within a process has a significant impact on group dynamics. If a group is too small, there may not be enough input of information and ideas to explore the problem thoroughly and create a range of potential solutions. If a group is too large, there is less opportunity for all participants to contribute, and reticent participants may not get an opening to be involved at all. Large groups also restrict the level of interaction – for example, public hearings are most likely to be one-way information provision rather than two-way deliberation. In larger groups it is more difficult for close relationships to form, which may affect the depth of discussion (see the section titled “Group Dynamics”).

Structure

The structure of the participatory process will depend on the decision situation, and what works in one situation might not work in another. Flexibility is often required to allow for a change in direction or to incorporate new information. General information can be communicated through the press and media. It is a good way of informing a large population in a relatively short time frame. It should also be noted that often the media report what they want to report and this may not be a balanced view of the situation and may have a detrimental impact on public perception. Other methods of communicating information include advertisements, postal letters, and E-mail. Face to face interaction ensures that the information communicated is understood, and body language provides the more subtle benefits of the information. Discussion of a problem is the best way to resolve conflict, and brainstorming generates solutions to a problem. The way in which a meeting is conducted may have an impact on the outcome of the meeting. Web-based participation tools are increasingly being used to involve the public in the decision-making process. As with most things they have their advantages and disadvantages. On the positive side, web-based tools can reach a much larger and geographically diverse group; information is available 24/7; they allow people to comment and express their views anonymously and in a nonconfrontational manner. On the negative side, people may be overwhelmed by the tools and have insufficient technical knowledge to use them; there is no mechanism to determine if the participants have understood and interpreted the given information correctly; although more people are using the Internet, access to the tools is not guaranteed. Web-based tools should be used alongside more traditional techniques to provide full participation.

The structure of the decision process should be considered when thinking about the structure of the participatory processes to be adopted. One method of structuring a decision process is to break it into three main phases: *issue formulation*, where data and material are gathered to give a clear and comprehensive picture of the issues involved in the decision. This stage lays the foundations for reaching a solution to the decision problem and is very important to the decision-making process as a whole; the *analysis* phase, where further investigation is made into the issues that are brought up in the first phase. A number of alternative courses of action to solve the problem can be postulated. These alternatives may be explored further with models that can predict an outcome given certain conditions; finally, the *decision* or *evaluation* phase, where the alternatives can be considered by the decision makers and a choice between alternatives can be made. This three-stage process can be repeated to ensure that all of the issues and alternatives relevant to the decision are explored to ensure that the decision is requisite (see Figure 2).

Stakeholder participation may be involved in one or more of these phases of the decision process, depending on the objectives of the decision maker.

Group Dynamics

It is important to appreciate the dynamics of any group of people that are assembled together and the effect this might have on the process outcome. There are a number of factors to consider [36, 42]. The group size and the number of participants involved in the process have a significant impact on the outcome. The balance between individuality and group behavior varies depending on the size of the group.

Figure 2 Three-stage methodology of decision [Reproduced from [41]. © The Institute for Operations Research and the Management Sciences (INFORMS), 1989.]

A group of 2–6 people can be classed as an “intimate group”, where individuality of participants is maintained. A group of 7–15 constitutes a “small group” in which individuality is preserved, and yet group processes emerge and exert considerable influence. A group of this size is small enough to work toward consensus but large enough to be representative. All participants have good opportunity to express their views, and differences of opinion can be used constructively to generate new perspectives. With groups of more than 15 participants, group processes dominate and individuality is submerged. The larger the group, the more difficult it becomes to reach consensus. Group cohesion is important, but maintaining some individuality will help the group remain creative. When the group is together, it has a character or personality as well as an emotional life. The emotional life affects how the task in hand gets done. An individual’s behavior may be influenced by the role that he/she has assumed, knowingly or unknowingly. Typical roles include the expert, the skeptic, the clown, the savior, the prophet, the critic, the mother, the protector, the warrior, and the leader. All these have an impact on the group life and interaction between participants. As participants begin to interact, differences between them (such as status, influence, role, and ability) may appear. As participants become more familiar with the decision situation, and the information they are provided with, barriers between them start to break down. McKenzie and Hunt describe the flow of conversation changes in a typical dialogue [39]. People begin by being polite with one another, both as a courtesy and as a way of gauging the reactions of others. Politeness breaks down into disagreements and individuals affirm their positions. As discussion progresses, participants question their positions, and begin to distance themselves from them. It is then possible to have dialogue that is open and not influenced by other agendas, where participants gain an understanding of others and the discussion can move forward. The process can be smoothed out and rendered more effective by the use of a neutral facilitator or moderator, at least in small groups [32, 36, 43]. Factors in group dynamics, such as flow of communication, perception of status, and emergence of leadership, are influenced by the physical position of group members, their distance apart, and their body orientations. These are affected by the shape and size of the room where a group meets,

and the spatial arrangement of chairs and tables. A lack of tables may be threatening to some but usually encourages openness and informality. Equally spaced chairs in a circle create a level playing field for all participants. When the environment and the arrangements for using it are focused, the group focuses more readily.

Other Important Characteristics

Participants may only be willing to contribute if the information they supply is kept anonymous and/or confidential. It should be established early in the introductory phase that such wishes will be respected. In some cases, the source of information may add weight to an argument. Permission must be granted before a source is identified. Ownership of the process and who runs it are important. The process is more transparent and legitimate if it is run by an independent facilitator, rather than someone who has some involvement or interest in its outcome. However, the authority usually has ultimate responsibility for the outcome and its implementation. For transparency, it should be clarified to all participants as to what will be done with the information they provide. Publishing a summary of the process can help people reflect, help with understanding of the issues, and help build consensus [44]. If comments are to be summarized and published, it should be considered which body is the appropriate body to handle the information. An authority may face criticism for protecting its own interest if they publish an outcome that is favourable to themselves. For example, in an online Environmental Protection Agency (EPA) (of the USA) participation process, the EPA was criticized for downplaying negative comments [4, 8]. The summary would be more legitimate if information is handled by a neutral facilitator.

Public Participation Processes

There is a wealth of literature describing various public participation processes. Table 1 describes some examples of conventional participation processes, and Table 2 gives some examples of some electronic (e-) participation tools. To achieve a set of objectives for the participation exercise, a combination of both conventional and e-participation tools can be

Table 1 Some examples of conventional participatory processes [3, 8, 11, 14, 23, 36, 42]

Participatory process	Description	Objectives
Referenda	A vote. Voters choose from available options and each vote cast has the same weight – all participants have equal influence. The vote is open to all members of the eligible voting population. Can be used in a number of situations to voting in a new government to community-based decision making.	Referenda should be representative, democratic, and acceptable to the population. The demand on resources will vary depending upon the context. Referenda do not necessarily produce structured decision making or a balance or risks or benefits as a vote can be cast without deliberation.
Public hearings/enquiries	A forum to inform the public about a particular situation; this could be a consultation on changes to regulation or a local development.	Public hearings are for sharing information. They are often viewed as a public relations exercise and have little influence on the outcome of decision making.
Consensus conference	A group of 10–16 participants representative of the population is brought together with experts in the area of the topic being discussed. The discussion is facilitated and participants discuss and try to reach consensus. The meetings are open to the public. The outcome can directly influence the development of legislation.	Difficult to represent the population with a group of 10–16 participants. It goes some way to involving the public in decision making that is well structured and of good quality; therefore, the outcome can be trusted.
Citizens jury	A group of 12–24 participants representative of the population is selected to meet over several days as part of a jury. The lay panel question expert witnesses mediated by a facilitator. Juries are not open to the public. The purpose is to reach a decision or formulate a set of recommendations.	Difficult to be representative of the population with 12–24 participants. The outcome is well-structured, quality decision making. It has a relatively high demand on resources.
Workshops	A facilitated workshop is an intensive session or working meeting attended by 7–15 stakeholders with different fields of expertise to discuss and share information.	Good for determining what the issues are related to the discussion. Good for developing a shared understanding. Not representative.
Focus groups	Used to gather opinions and attitudes about general topics. Groups of 5–12 people have free discussion. No decision-making role for participants.	Representative of specific groups; different groups can bring valuable information on the topic. All about information gathering.

complimentary. For example, an in-depth discussion to formulate the issues with a small group of individuals followed by a wider discussion over the web will increase representation of different groups. It is not expected that all objectives will be achieved with one process or that all objectives are important in all contexts. While there are a large number of studies focused on the performance of individual

mechanisms, there has been very little comparison of different participatory processes in the literature to determine which participatory tool works best for a given scenario. Bayley and French [47] attempted to make a comparison between processes in terms of how they met a list of objectives. However, as noted in the paper, the judgments of effectiveness are based on what little evidence could be gathered

Table 2 Some examples of electronic participatory tools and processes [21, 45, 46]

Participatory process	Description	Objectives
Online discussion forums	These enable an unlimited number of people to discuss one or more topics asynchronously.	Are anonymous so the discussant cannot be identified. Inappropriate additions to the forum can be censored, however this might bring into question the democratic values of the process.
E-voting	Online voting	Technology still being developed to ensure that the votes are cast by those that are eligible, and that the vote is secure.
E-polling	Online opinion polling	Can be useful to gauge opinions of the online community on particular matters.
Geographical information systems (GIS)	Provides an ideal infrastructure to debate geographically referenced issues. Such systems can be web enabled to allow the public and stakeholders to take part in a planning process and enhance participation in the decision-making process.	High resource demand. Possibility that people will interpret the information in different ways. Needs to be combined with an effective human–computer interface. Can be very useful for people to picture the geographics of a situation and have an input.

from the literature, from experience, and occasionally little more than common sense – the comparison was based on judgment rather than empirical evidence.

The task of the designers of a participatory process is to consider the situation and identify the objectives that matter to them in that context along with their relative importance. The appropriateness of such a process is context specific. For instance, in the case such as the withdrawal of an exemption license for a pesticide, there would be little urgency and the timescale of the participatory process could be relatively relaxed, whereas dealing with a situation that was potentially a threat to health would have more urgency. In the former emphasis would surely be on exploring public and stakeholder values and checking against a wider set of perceptions for possible unanticipated consequences, whereas information provision and advice would have a higher importance in the latter. Thus the design process can be seen essentially as a standard decision analytic process where the analysis is conducted using an additive multiattribute value function. A design process may follow these steps:

1. discuss and identify the issues and concerns, exploring the context from a variety of perspectives, for instance, using soft modeling techniques to facilitate discussion [48, 49];
2. discuss and identify the objectives' hierarchy describing the authority's goals for the context [48];

3. develop a number of alternative processes, which draw on a variety of mechanisms to meet the objectives;
4. score the alternative processes against each objective [50];
5. evaluate the relative importance of the objectives through appropriate weights, e.g., using swing weighting [50];
6. form overall weighted scores for each alternative process, thus ranking them;
7. explore the sensitivity of the resulting ranking to changes in scores and weights [51–53].

More complex evaluations introducing key uncertainties are also possible [51, 53, 54].

Case Studies Involving Stakeholder Participation

The Lake Päijänne Case

Lake Päijänne is the second largest lake in Finland and has been regulated since 1964 to increase hydropower production and decrease agricultural flood damages [5]. The lake has extensive recreational housing developments along the shores and there are thousands of recreational users and fishermen on the lake. Problems currently recognized on Lake Päijänne include the low water levels during spring, changes in the littoral zone vegetation, and

negative impacts of the regulation on the reproduction of fish stocks.

An extensive multidisciplinary research project was carried out between 1995 and 1999 to reevaluate the regulation policy of Lake Päijänne. The aims of the project were to assess the ecological, economic, and social impacts of the regulation. Stakeholder's opinions were sought about the current regulation and its development, comparison of new regulation policy options, and recommendations to diminish the harmful impacts of the regulation. At the beginning of the project there was wide distrust, especially among fishermen, toward the project and the organization responsible for it. Therefore, an open and participatory planning process was considered to be necessary in order to gain public support for the project and to find a consensus solution for further regulation strategy. The overall objective was to achieve consensus on the recommendations for the regulation policy through improved understanding of the complex nature of the regulation problem and of the other interest groups' preferences.

A number of participatory mechanisms were utilized to involve stakeholders in deliberation. A steering group consisting of 18 representatives of different stakeholders was set by the Ministry of Agriculture and Forestry. Four working groups were established to improve the communication between the water resource authorities, local stakeholders, experts on regulation, and researchers. To inform the public, a local press conference was arranged after almost every steering group meeting. Five public hearings were arranged at the beginning of the project and five at the end of the project. A mail questionnaire was sent to over 2000 users of the watercourse to determine the quantity and quality of recreational use of the area, problems related to water use, and objectives for future regulation practice. In addition to this, web tools were used to support the process and enable people not attending the workshops to access the results. An essential part of the participation process was decision analysis interviews of the extended steering group.

The results of the interviews were applied to prioritize the objectives of regulation in the different water conditions. This information was further used when the final consensus recommendation for the sustainable regulation strategy for Lake Päijänne was created. The draft recommendations were compiled by the experts and authorities responsible for the

management of Lake Päijänne. These were presented, discussed, and revised in the steering group meetings and finally unanimously accepted by all representatives. The implementation of the recommendations was relatively easy because all major stakeholders committed to the outcome of the process.

The Case of UK Energy Policy

In 2002 the Department for Trade and Industry (DTI) carried out a wide consultation on UK energy policy [55]. The evaluation was to determine the energy-related goals that matter most to citizens in the United Kingdom, what their attitudes toward different energy sources are, and what measure they would like to see implemented to enhance these goals. The consultation process was organized in four streams: web-based expert consultations; survey-based consultation of stakeholders with special interests; focus groups; and deliberative workshops with members of the general public. The aim of the former three processes was to gather information about the main concerns from the respective groups. The aims of the deliberative workshops were to gain an in-depth understanding of the public's perspectives about future national energy policy; to determine the objectives that the public considers crucial for the provision of electricity, and the trade-offs between the objectives; to establish the public's attitude toward nuclear energy, renewable energy technologies, and energy efficiency enhancement; to determine ways to achieve these objectives, i.e., the roles of government, companies, and individuals; and to evaluate the processes of public debate, public information, and policy making in the future and how information changes the participants' attitudes to electricity generation.

The outcome of the deliberation was strong support for enhancing the use of renewable energy sources to produce electricity and for increasing energy efficiency while keeping an eye on energy costs. All participants wanted a change to current trends. Attitudes to nuclear power were split: some participants thought that it should be part of a mix of energy sources utilized and others wanted to end it as a matter of principle. The majority of participants could not foresee a solution to the nuclear waste problem. Diversity of energy sources was perceived as important for security of supply. Over the course of the workshops, participants changed their minds

to some extent about which renewable energy technologies they preferred, given the information they received about costs and benefits of each option. Wave and wind power tended to rise in comparison with solar energy, probably reflecting the higher costs. Participants saw a major role for the government in changing behaviors; policy suggestions included measures to sell only goods that were energy efficient. Education of young people and adults was considered to be the most effective way to encourage households to use less energy. There was also clear support for the introduction of higher taxes to encourage people to purchase energy-efficient goods.

Public Participation Using Web-Based Geographical Information Systems (GIS): Local Planning in Slaithwaite

The Neighbourhood Initiatives Foundation (NIF) in the area of Slaithwaite in West Yorkshire, UK, aimed to involve local people in local environmental planning problems and decision making. The local community created a large-scale map of the area onto which local people put flags with their ideas. An event “Shaping Slaithwaite” was held at the village fair, where people were given the opportunity to have their say on their community. Alongside this, a web-based geographical information systems (GIS) map was created to allow wider participation [45]. GIS is used to help people visualize problems that involve a special element using electronic maps.

The web-based system was found to be popular; however, the user group was not representative of the population. Many more males than females used the system; occupation information collected suggested a strong weighting toward professional/managerial and educational positions; and the age range showed a heavy skew toward school children (due to educational uses of the web tool). Other problems encountered include the lack of familiarity with the technology involved and the lack of Internet access to all sectors of the population.

Summary

Participation processes can be adopted to involve stakeholders in decision-making processes, including the management of risk and the development of risk mitigation strategies, as demonstrated in the case studies.

Quantitative Reliability Assessment of Electricity Supply

The basic function of an electric power system is to satisfy its customer load demands as economically as possible and with a reasonable assurance of quality and continuity. Evaluation of the level of assurance of quality and continuity is known as *reliability assessment* [1]. Figure 1 shows the three functional zones of generation, transmission, and distribution that constitute an electric power system [2].

In a vertically integrated system, these facilities are owned and operated by a single entity. In the deregulated environment, there could be many owners and subsystem operators, and therefore, overall long-range planning has some difficult challenges. Power systems normally contain redundant facilities in the various functional zones to provide a reasonable level of reliability of supply to the customer, and the economic and reliability constraints can be quite competitive. This is not a new problem and has existed since the creation of electric power supply systems.

The functional zones shown in Figure 1 can be combined to create hierarchical levels to facilitate system analysis, planning, and operation. Hierarchical level one (HLI) involves the generation facilities, and reliability analysis at this level is concerned with the ability of the system to generate sufficient power to meet the overall electrical power and energy demands. Hierarchical level two (HLII) involves the composite generation and transmission system (bulk electric system), and analysis at this level is concerned with the ability of the system to deliver the required energy to the bulk supply points. The hierarchical level three (HLIII) includes all the system facilities. Detailed quantitative analysis at HLIII is not normally conducted because of the enormity of the problem in a practical system. Detailed analysis is, however, usually conducted within the distribution functional zone. The actual level of redundancy in the physical facilities decreases as the focus moves through the generation, transmission, and distribution functional zones, and most load points are served by radial networks at the actual customer level. This could include extensive

manual or automatic switching provisions to decrease the duration of supply failures but the primary supply is still radial in nature. Statistics produced by the Canadian Electricity Association (CEA) indicate that in Canada, 82% of the interruptions seen by a customer in 2005 occurred because of failures in the distribution functional zone [3]. The overall level of reliability is quite high and any proposed improvement in reliability must be balanced with the commensurate economic cost of attaining the improvement. Considerable work has been done in the area of reliability cost/worth analysis in attempts to determine how reliable should electricity supply be in a modern society [1].

Quantitative reliability assessment of electricity supply is an important area of activity in modern power systems. The criteria and the resulting techniques to assess and incorporate reliability concerns in the planning and operation of electric power systems were, initially, all deterministically based and some of them are still in use today. Percent reserve margin and the loss of the largest unit criteria were used to determine the required generating capacity at HLI. Transmission system analysis is still largely based on the ability of the system to meet the peak demand with any one transmission element out of service. This is commonly known throughout the world as the $n - 1$ criterion and is sometimes extended to include additional elements, i.e. $(n - m)$. The system investment costs and the system reliability, however, increase as m increases, and again it becomes a question of how reliable should the system be. Deterministic techniques are usually relatively simple to appreciate and to apply. They are, however, quite inconsistent, as not all elements have the same likelihood of failure or have the same impact on the system. Deterministic techniques, in their basic form, do not and cannot incorporate the inherent probabilistic or stochastic nature of system behavior, such as component failures, adverse weather, and future customer load demands. This has been understood and appreciated for many years and considerable effort has been devoted to the development of probabilistic techniques that respond to the actual factors that influence the reliability of electric power supply. A considerable number of publications available on this subject are illustrated in [4–10].

Most electric power utilities collect considerable system and component data to monitor past reliability performance and to provide the ability to predict

Figure 1 Functional zones and hierarchical levels

the future performance. Collecting data is expensive but necessary, as these data are the foundation for past assessments and future estimates of the system's ability to serve its customers. These data are used in the probabilistic analysis of existing and proposed system facilities and provide valuable input to system expansion planning and the resulting decision-making processes. In Canada, generation and transmission component data are collected, analyzed, and disseminated by the CEA using comprehensive and consistent protocols [11, 12]. Similar systems exist in other jurisdictions.

Quantitative power system reliability assessment can be conducted using a variety of methods. These methods are generally categorized as being either analytical or simulation techniques. Most of the earlier work was done using analytical approaches. The increasing availability of high-speed computing facilities has, however, made simulation techniques a powerful and practical option for many studies. Analytical techniques represent the system and its components by mathematical models, which are used to compute the required reliability indices using direct numerical analysis. The obtained reliability indices are usually expected values. Simulation methods are usually designated as Monte Carlo simulation (MCS) (*see Numerical Schemes for Stochastic Differential Equation Models; Systems Reliability; Cross-Species Extrapolation; Bayesian Statistics in Quantitative Risk Assessment*) [13] and are used to estimate the reliability indices by simulating the random behavior of the individual system

components and the overall system. MCS can be divided into two general approaches. The state sampling approach can be used to determine the state (available or unavailable) of each component and the resulting state of the system. A suitably long series of trials is conducted and the resulting reliability indices are estimated. The sequential sampling approach examines the behavior and history of each component and the system in chronological order for a suitably long period of time. The reliability indices are then estimated from the system-simulated history. Durations of the up and down state of the component are determined using the probability density functions of failure and repair time. Theoretically, sequential MCS is a very powerful technique that can incorporate virtually all the aspects and contingencies associated with an actual system. It can be used to generate reliability index probability distributions in addition to the expected values. The required simulation time to analyze a large practical system can, however, be quite lengthy even with modern high-speed computing facilities.

Quantitative Reliability Assessment at HLI

A basic requirement in achieving acceptable reliability in a modern electric power system is that the system generating capacity exceeds the customer load requirements by a suitable margin. Reliability studies can be generally divided into the two categories of

adequacy and security analyses. The North American Electric Reliability Council (NERC) defines adequacy as “the ability of the electric systems to supply the aggregate electrical demand and energy requirements of their customers at all times, taking into account scheduled and reasonably expected unscheduled outages of system elements” [14]. Adequacy evaluation involves static or steady-state analysis, and dynamic conditions are normally incorporated in security evaluations. Generating capacity reliability evaluation is generally focused on the adequacy domain.

The most commonly used probabilistic generating capacity adequacy indices are the loss of load expectation (LOLE) and the loss of energy expectation (LOEE) [1]. The LOLE is the most popular index and is the expected number of hours or days in a given year that the system load will exceed the available capacity. The predicted risk indices are not applicable to individual customer load points and apply to the total load in the system under study. Most applications involve a daily peak load model rather than an hourly load model, and an annual period. The risk index in this case is, therefore, the expected number of days per year that the daily peak load exceeds the available capacity. A common criterion is 0.1 days yr^{-1} . The reciprocal of this index is “1 day in 10 years” and is often used to express the criterion. The risk can also be expressed as the loss of load probability (LOLP). An index of 1 day in 10 years does not imply that there will be a generating capacity shortage on average once in a 10-year period. The LOLE is not a frequency index. This is a common misconception and one that seems to exist in general application. Techniques are available to estimate the average frequency of capacity deficiencies using either analytical models or Monte Carlo simulation [1, 13]. These techniques are well developed but require considerably more system data than does the basic loss of load approach. The basic procedure used to assess generating system adequacy is relatively standard in concept and is based on the creation of suitable generation and load models [1]. The generation and load models are combined (convolved) to create a risk model.

There are certain basic factors that should be included in a comprehensive assessment of generation system adequacy. The following is a quotation taken from a recent NERC regional standard.

“Among the factors to be considered in the calculation of the probability are the characteristics of the loads, the probability of error in load forecast, the scheduled maintenance requirements for generating units, the forced outage rates of generating units, limited energy capacity, the effects of connections to the pools, and network transfer capabilities.”

The relatively recent rapid growth in renewable energy related generating facilities and the anticipated considerable future growth clearly dictate the need to accurately incorporate these facilities in generating capacity adequacy evaluation. Considerable attention is being given to wind turbine units at the present time. These units can be considered to be capacity limited owing to the diffuse and random nature of the wind. Conventional generating units, other than perhaps hydro units on a controlled single river system, are usually considered to be independent. This is not the case with wind turbine units in a wind farm. These units are basically all dependent on the same wind regime. This is an important element in the adequacy assessment of a wind generator farm. The degree of correlation between multiple wind farms is also an important factor in adequacy assessment of overall generating capacity.

The basic techniques used to conduct conventional generating capacity evaluation are extremely flexible and can be modified and extended to include new constraints, criteria, and requirements associated with the new utility environment. A key requirement, however, in quantitative reliability evaluation is the availability of consistent and comprehensive data on relevant equipment, load characteristics, and system constraints. Databases such as the equipment reliability information system (ERIS) maintained by the CEA and the generation availability data system (GADS) operated by NERC are valuable repositories of utility data and equipment reliability parameters. Similar systems exist throughout the world.

Quantitative Reliability Assessment at HLII

As noted earlier, the determination of how much generating capacity is required to provide a reasonable level of reliability is a fundamental element in power system planning. An equally important planning requirement is to develop a suitable transmission network to transport the required energy to the bulk

electric system supply points. The energy is then conveyed through the connected distribution facilities to the customer load points. The bulk transmission facilities must be capable of maintaining acceptable voltage levels, loadings within the thermal limits of the transmission facilities, and the system stability limits. The static assessment of the composite generation and transmission system's ability to satisfy the load requirements is designated as adequacy assessment and has been the subject of considerable development [4–10]. A wide range of probabilistic techniques have been developed and applied using both analytical methods and MCS. The bulk of the computation time is used in the solution and resulting examination of the system state under the outage states of various components. A wide range of load point and system indices can be calculated at HLII. The most popular indices are the probability of load curtailment (PLC) and the expected energy not supplied (EENS). These indices are similar to the LOLP and LOEE indices used in HLI assessment, respectively.

The energy-based indices (LOEE and EENS) can be extended to assess the expected customer interruption costs (ECOST) at individual load points and at the system level using an interrupted energy assessment rate (IEAR) expressed in dollars per kilowatt-hour of unserved energy. The ability to quantify the reliability of a bulk electric system provides the opportunity to estimate the reliability cost associated with a particular system configuration. The monetary cost of system unreliability can be included with the capital, operating, and maintenance costs in the examination of system planning options.

Quantitative Reliability Assessment at HLIII

There is relatively little practical application of quantitative predictive reliability assessment at HLIII, although some research has been conducted in this area. The basic approach is to utilize the indices obtained at a bulk system load point as supply indices in series with the actual distribution system. Quantitative assessment of past reliability performance at HLIII is conducted by many distribution utilities throughout the world. The resulting indices are known as *service continuity statistics* in North America, and are collected through the CEA [3] in Canada. The basic service continuity indices used throughout

North America and in many other places in the world are as follows:

SAIFI: system average interruption frequency index;

SAIDI: system average interruption duration index;

CAIDI: customer average interruption duration index;

IOR: index of reliability.

The aggregated statistics for Canadian electric power utilities are typical of the service continuity levels in most developed countries around the world. The following indices are the annual values for 2005:

$SAIFI = 2.13$ interruptions/system customer;

$SAIDI = 4.80$ h/system customer;

$CAIDI = 2.26$ h/customer interruption;

$IOR = 0.999452$.

Quantitative Reliability Assessment – Distribution

Predictive techniques for reliability assessment in the distribution functional zone are highly developed [1]. Both analytical and MCS techniques have been applied to estimate the reliability at individual load points and the service continuity statistics used to measure past performance. The focus at the customer level is on physically based indices that can be readily interpreted by the customer. The most common indices are the frequency of failure, the duration of failure when it occurs, and the unavailability of supply in hours per year. Analytical techniques are used to provide the expected value of these parameters. Sequential MCS can be used to determine the expected values and the probability distributions associated with the annual performance. These techniques have been extended to include the customer interruption costs associated with power supply failures. The ECOST values are used in reliability cost/worth analyses associated with system modifications, reinforcements, operating considerations, and long term planning. Many countries around the world have conducted intensive surveys of their customers to determine the cost of power failures [15]. The resulting data have been used in a wide range of tasks including reliability cost/worth evaluation, optimum reliability level determination, and penalty payments for supply failures.

R&D Planning and Risk Management

Research and development (R&D) projects are inherently risky. Investors in R&D projects are often uncertain about the probability of eventual technical success, the costs and time needed to succeed (if success is possible), competitor activities, and market acceptance and financial rewards if a technical success occurs. Quantitative risk models can help characterize and manage R&D risks and answer such practical risk-management decision questions the following:

- *R&D project scheduling and management*: what part(s) of a project to work on first, how to order the activities within a project, decision rules for when to abandon a project
- *R&D project selection*: which projects to fund?
- *R&D investment strategy*: how intensely or quickly to pursue R&D?
- *R&D and intellectual property*: how to manage the results of R&D (e.g., through licensing and patent systems) to create incentives that will benefit society?

This article surveys methods for quantifying and managing R&D risks.

Minimizing R&D Project Risks by Optimally Ordering Activities

A very simple model of an R&D project divides it into multiple activities, each having a known cost to attempt it and a known probability that it can be successfully completed if it is attempted. An R&D manager may wish to minimize the expected cost to either successfully complete the whole project or to learn (by trying activities and learning that they fail) that it cannot be completed. The problem of sequencing the project activities to achieve this goal can be solved easily in certain cases.

Example: Optimal Sequencing of Activities in an R&D Project

Setting: Suppose that an R&D project can be completed successfully only by successfully completing

both of two activities, A and B. The cost to attempt activity A is $c_A = 1$ cost unit; the cost to attempt B is $c_B = 2$ cost units; and the conditional probabilities of successfully completing these activities, if they are attempted, are $p_A = 0.8$ and $p_B = 0.5$, respectively. The two activities may be attempted in either order. The value of successfully completing the project (i.e., of successfully completing both A and B) is $V = 10$ benefit units (on a scale commensurable with the cost units).

Problem: (i) What investment strategy maximizes the expected value of investment in this set of R&D activities? (ii) What is the expected value of this R&D project?

Solution: (i) Attempting A first, and then B if A succeeds, yields an expected net value of (cost to attempt A) + (probability A succeeds) $\times$ (cost to attempt B after A succeeds + probability that B succeeds $\times$ value obtained if B and A succeed) which is given by

$$\begin{aligned} & -c_A + p_A \times (-c_B + p_B \times V) \\ & = -1 + 0.8 \times (-2 + 0.5 \times 10) = 1.4 \text{ units} \quad (1) \end{aligned}$$

Symmetrically, attempting B first, and then A if B succeeds, yields an expected net value of

$$\begin{aligned} & -c_B + p_B \times (-c_A + p_A \times V) \\ & = -2 + 0.5 \times (-1 + 0.8 \times 10) = 1.5 \text{ units} \quad (2) \end{aligned}$$

Since 1.5 is the higher value (and is positive), the optimal strategy is to attempt B before A, and the expected monetary value of the R&D project (if the optimal strategy is used) is 1.5.

More generally, trying A before B yields a higher expected value than trying B before A if and only if

$$\begin{aligned} & -c_A + p_A \times (-c_B + p_B \times V) > -c_B + p_B \\ & \quad \times (-c_A + p_A \times V), \text{ or, equivalently,} \\ & \text{if } c_B \times (1 - p_A) > c_A \times (1 - p_B) \quad (3) \end{aligned}$$

That is, for a project with positive expected value, activities should be attempted in order of decreasing failure probability per unit cost ratio (i.e., in order of decreasing $c_i/(1 - p_i)$, where $i = A$ or B in this example); this decision rule holds for any number of activities. [Projects with negative expected value should not be attempted at all, if the goal is to maximize expected value. The expected value of

a sequence of N consecutive activities is found by summing over all activities 1 through N , the probability of failing for the first time at that activity times the net financial loss from doing so, and then subtracting that number from the overall success probability (which is the product of the success probabilities of all activities in the sequence) times the net benefit ($= V - \text{sum of activity costs}$), if the project succeeds.]

The preceding example is especially simple because completing the project required all of the activities in it to be completed. The only decision was the order in which to attempt them. More generally, there may be several alternative ways to successfully complete an R&D project. A subset of activities is called a *path set* if completing all of the activities in it suffices to successfully complete the project. A *minimal path set* is one in which no proper subset of activities is a path set. The project succeeds if and only if all of the activities in at least one minimal path set are successfully completed. If minimal path sets are disjoint, then an optimal (expected value maximizing) investment strategy is to attempt alternative minimal path sets in decreasing order of success probability per unit expected cost (where the success probability for a minimal path set is the product of the success probabilities of the activities in it and the expected cost of the minimal path set is calculated assuming that activities *within* each minimal path set are sequenced in decreasing order of failure probability per unit cost ratio, as in the preceding example). Investment in a project should cease as soon as no minimal path sets with positive expected value remain.

These ideas can be extended to projects in which activities cannot be attempted in any arbitrary order. Suppose that precedence constraints among activities restrict the order in which they may be attempted: it may be necessary to complete some before others can be attempted. Suppose that these constraints are represented by some acyclic graph, where each edge represents an activity and each activity can be attempted if and only if all of its predecessors have been successfully completed. The project succeeds and its benefit is obtained, if and only if at least one path is successfully completed from a starting activity (one with no predecessors) to an ending activity (one with no successors). In this quite general framework, the optimal (expected utility maximizing) investment strategy for a decision

maker with linear or exponential utility can still be found by assigning to each activity a number called its *index* (generalizing the failure probability per unit cost ratio in the preceding example) that can be computed quickly from the cost to attempt, success probability, and precedence constraint data. The optimal decision rule is to *attempt activities in order of decreasing index until either success is achieved or no activities with positive indices remain* [1]. Many other extensions of index policies (also called *Gittins index* policies) have been developed for situations with discount rates, randomly evolving opportunity sets, and relatively sophisticated models of risky projects, such as Markov decision processes and multiarm bandit decision problems [2, 3].

Optimizing R&D Project Portfolios

Optimally sequencing the activities within an R&D project can minimize the expected cost to complete it or to discover that it cannot be completed; more generally, it can maximize the expected utility of investing in the project. But even after such within-project optimization, the problem of choosing a subset of available R&D projects to fund – often from many proposals – remains. Quantitative approaches to optimizing investment in proposed risky R&D projects to maximize resulting net benefits over time include the following:

1. Combinatorial optimization models

These search for combinations of select and reject decisions to maximize the net value of the selected portfolio of projects, given budget constraints and possible interactions and dependencies among the projects. Large-scale, nonlinear, 0–1 programming, and mixed integer programming models have been developed for this purpose and are practical with current optimization technology and computational resources [4, 5].

2. Improving an existing portfolio

Ringuest *et al.* [6] consider the financial impacts of changing an existing portfolio by adding or deleting projects, taking into account how such additions and deletions shift the predicted (simulated) probability distribution of net return from the entire project portfolio and taking into account interactions among projects.

3. Continuous dynamic optimization

Loch and Kavadias [7] propose a dynamic model of resource allocation for projects that may have statistically dependent, dynamically evolving market payoffs, assuming that partial investment in a project can generate partial returns. In this setting, explicit optimal investment formulas can be developed and interpreted in terms of equating appropriately defined marginal returns across investments in different projects.

In general, optimization of R&D project portfolios when there are strong interactions among projects (e.g., because of shared subsets of activities, or interdependencies among their technical success probabilities, and/or market values if successfully completed) provides a rich set of challenging problems for sophisticated, computationally intensive, optimization-based approaches to risk management. Promising approaches include simulation optimization and robust and multicriteria optimization methods for portfolio selection, together with financial evaluation models that recognize the real option value of risky projects that can be abandoned if they become unattractive. The pharmaceutical and energy industries have developed and applied many such models [8]. From the practical point of view, R&D portfolio optimization models can require potentially burdensome input data on project investment opportunities and their interactions. To ease this burden, some recent work has explored the use of approximate (fuzzy) descriptions of potential future cash flows in assessing project portfolio values in a real options framework, leading to a fuzzy mixed integer programming model for optimization of R&D portfolios [5].

Owner versus Manager Incentives in R&D Project Management

In the simplest case of a single minimal path set and no precedence constraints, as we have seen, expected value is maximized by attempting the “most risky” or “most difficult” activities first, meaning those with the highest failure probability per unit cost ratios. This strategy minimizes the expected cost of discovering that success is impossible, if that is the case. (Since project success requires completing all activities, the expected net benefit from success

does not depend on the order in which activities are attempted; thus, focusing on minimizing the expected cost to discover failure, if success is not possible, is an appropriate goal.) However, rewarding a manager for successfully completed activities may create an incentive to postpone high-risk activities as long as possible, increasing the manager’s expected reward but increasing the expected cost of unsuccessful projects. R&D projects that should be abandoned may be continued too long if managers postpone attempting high-risk activities until ones that are more likely to succeed have been completed. Conversely, R&D managers may abandon projects too soon and/or may invest too little effort in making them succeed (from the owner’s perspective) when effort and success probability are the managers’ private information.

Such incentive problems (which are instances of moral hazard and principal–agent conflict problems) can be largely overcome by evaluating partially completed R&D projects using a real options framework and then compensating R&D managers according to these evaluations. More specifically, compensating R&D managers using appropriate adjusted residual income measures (with capital charge rates that are contingent on manager reports of estimated profitability, recognizing that these may be distorted by managers in an attempt to obtain greater compensation) allows an effective separation of R&D investment decisions by owners and effort allocation decisions by R&D managers. Such compensation rules optimally balance incentives to invest in risky R&D against incentives to abandon unfavorable projects in some specific models of owner and manager information and incentives [9].

Optimal Intensity of Investment in Competitive R&D Projects

When a company undertakes R&D to obtain a competitive advantage, time pressure from competition (especially in a “winner takes all” patent and intellectual property environment) may make it worthwhile to invest simultaneously in multiple alternative approaches (e.g., in multiple minimal path sets). This stochastically reduces the time, but stochastically increases the cumulative expenditure, until either success is achieved or no attractive paths forward remain.

Exactly how intensely a company should invest in R&D to maximize expected profit depends on

how intensely competitors invest. Hence, quantitative models of optimal investment intensity are often formulated as differential games in continuous time, with the competing firms deciding at each moment how intensely to invest in R&D based on information available so far. In such competitive R&D models, details of R&D project activities are typically suppressed, and R&D projects are represented by relatively simple models, e.g., functions showing how the cumulative probability (or, equivalently, the hazard function) for successful completion of a project varies with the cumulative amount invested. In these models, incremental investment purchases incremental success probability, and more rapid expenditures hasten the time until either success occurs, it becomes optimal to abandon the project, or no investment opportunity remains. Typical conclusions from such models are as follows:

- Competitive rivalry increases R&D spending by each competitor when the benefits of the first breakthrough are captured by the firm that achieves it [10].
- If patent protection is incomplete (e.g., reflecting positive externalities from increased knowledge) and/or there are opportunities for licensing, so that the benefits of innovation may be shared even by noninnovators, then the effects of competition on the overall pace of innovation are ambiguous. Only some firms may invest in R&D, and social welfare may be either increased or decreased compared to the “winner takes all” situation [11].

Such strategic models of competitive R&D investment and resulting project value complement *real options* approaches that treat competitor actions as exogenously specified and then optimize a firm’s abandonment decisions (i.e., choice of when and whether to exercise the “option” to abandon). Such models typically assume that remaining cost to complete is uncertain and evolves according to a random process as R&D proceeds [12].

Conclusions

R&D portfolio selection, project management, and incentive design problems pose challenging practical applications for quantitative risk-management methods. The stakes for effective risk-management

methods in R&D are high, as the same set of risky R&D project opportunities can lead to either profits or losses, depending on how well the risks are managed through project selection and management.

Although sophisticated quantitative methods for modeling and managing R&D risks have been developed, as summarized in this article and pursued further in the references, applying such methods in practice, with realistically limited and uncertain data and estimates of potential future R&D costs and benefits, continues to be challenging. Yet, it is of great importance in areas such as pharmaceuticals, high technology, and energy, where portfolios of risky projects often drive company value. Therefore, further development of practical methods for R&D risk characterization and risk-management decision making will probably remain an active and rewarding area of both theoretical and applied risk management in the foreseeable future.

Radioactive Chemicals/ Radioactive Compounds

Materials are made up of atoms, and key subatomic particles are called *neutrons*, *protons*, and *electrons*. The central nucleus of each atom is made up of protons and neutrons, and electrons orbit the nucleus like planets orbit the sun. Some combinations of the subatomic particles are unstable. Radioactivity is the spontaneous transformation of an unstable atom to a more stable form, often with the emission of particles and energy that together are called *radiation*. Radioactive forms of elements are often called *radioactive isotopes* or *radionuclides*.

In common notation for radionuclides, the element symbol (such as Co for cobalt or N for nitrogen) is shown with a superscript number and sometimes a subscript number. The subscript is the atomic number, the number of protons in the nucleus of an atom. For a given element, the atomic number never changes. For example, all isotopes of uranium have an atomic number of 92. The superscript number is the atomic weight, which equals the number of protons and neutrons in the nucleus. For example, $^{235}\text{U}_{92}$ has 92 protons and $235 - 92 = 143$ neutrons in its nucleus. The atomic number is sometimes omitted when radionuclides are named in text or tables with just the element name or symbol and the atomic weight, such as sodium-24 or ^{24}Na .

The traditional unit of radioactivity, the curie, is equal to 3.7×10^{10} disintegrations per second, historically based on the radioactivity in one gram of radium-226. In the International System of Units (SI), 1 Becquerel (1 Bq) equals 1 disintegration per second.

Sources of Radioactive Compounds

Over 60 radionuclides are found in nature, and hundreds more can be made by man in devices such as reactors or accelerators. Compounds that include radionuclides can occur in nature and can also be synthesized by man. Radionuclides normally encountered by humans can be categorized by their origin as terrestrial, cosmogenic, or man-made [1].

Terrestrial radionuclides are found in the earth's crust. Several dozen naturally occurring radionuclides

decay very slowly, and are left over from when the earth was created. Some of these "primordial" radionuclides occur in series that decay through chains of radionuclides until a stable isotope is reached. There are three naturally occurring decay series:

- the uranium series – headed by uranium-238 (^{238}U);
- the actinium series – headed by uranium-235 (^{235}U); and
- the thorium series – headed by the thorium-232 (^{232}Th).

Cosmic radiation refers to the radiation from space, coming primarily from stars outside our solar system. Cosmic radiation can cause cosmogenic radionuclides to be formed through interaction with the earth's atmosphere and crust. Cosmogenic radionuclides include carbon-14, hydrogen-3 (also called *tritium*), sodium-22, and beryllium-7.

Anthropogenic radioactivity comes from human activities such as nuclear weapon tests and use, reactor operation and accidents (such as Chernobyl), and use of particle accelerators. Examples include tritium from weapons testing and fission reactors, reactor fuel reprocessing facilities, and nuclear weapons manufacturing; iodine-129, iodine-131, strontium-90, and cesium-137 from weapons testing and reactors; technetium-99, a decay product of fission product molybdenum-99; and plutonium-239 from reactors and particle accelerators.

Types of Health Effects from Radiation Exposure

Health effects from exposure to radiation fall into two categories. Deterministic effects occur only when a minimum dose or threshold is exceeded. Examples include reddening of the skin (erythema) and formation of cataracts. Once the threshold has been exceeded, the *severity* of the effect increases with dose. Ionizing radiation can damage genetically important molecules in cells, such as DNA, either directly (direct hit) or indirectly through chemical means. The damage to the DNA of a cell can result in the cell losing its ability to reproduce. The cell might eventually die, generally when division is attempted. If enough cells suffer lethal damage in an organ or tissue, there will be a loss of organ function.

Units of radiation dose in current use include the gray (Gy), the SI unit of absorbed dose in tissue; 1 Gy corresponds to absorption of 1 J of energy/kg of body tissue, or 100 rad in traditional units. The sievert is the SI unit of dose equivalent, which is the absorbed dose in gray multiplied by a quality factor that reflects the relative effectiveness of the different types of radiation in producing biological effects (1 Sv = 100 rem in traditional units). For a point of reference, the current occupational dose limit for adults in the United States is 50 mSv (0.05 Sv) per year total effective dose equivalent from external exposures to the whole body and from intakes of radioactive material [2].

Without quality medical care, the dose at which 50% of people will die within 60 days (the LD_{50/60}) is about 3–5 Gy (300–500 rad). If a small area of the body is acutely exposed to high doses, death may not occur but other effects may be seen. An acute dose of approximately 6 Gy to the skin from β radiation, such as from skin contamination, will cause sunburn-like reddening of the skin (erythema) within a week [3]. The threshold for temporary sterility in males is a single absorbed dose in the testes of about 0.15 Gy. Permanent sterility will occur in men if doses exceed 3.5–6 Gy, and in women when doses exceed 2.5–6 Gy [4]. Radiation-induced cataract formation has been observed following doses of over 0.5–1.5 Gy to the lens of the eye [5]. The thresholds discussed above are for acute exposures: in other words, doses delivered in a single, brief exposure. If the dose is spread out over a longer period of time, the effect will be less, as cells can repair much damage inflicted on them, if given time to do so.

For the other category of radiation effects, stochastic effects, the *probability* rather than the severity of the effect increases with dose. With stochastic effects, the nature of the harm arising from a low dose of radiation, if it occurs, is the same as that arising from a higher dose. While there is controversy regarding whether or not there are thresholds below which radiation exposures do not increase the likelihood of stochastic effects, for radiation safety purposes it is commonly assumed that any exposure to radiation, no matter how small, increases the probability that stochastic effects will occur.

If an irradiated cell is damaged, it might survive and be able to reproduce. However, if repair is not perfect, then mutations can result in the formation of

cancer cells or in the passing of faulty information to succeeding generations of cells. These are stochastic effects, and it is possible that the harm from a low dose of radiation will be just as great as that arising from a higher dose. However, the probability of that harm occurring is lower with the lower dose.

Heritable effects of ionizing radiation exposure have not been clearly demonstrated in humans. On the basis of studies in mice, it appears that the radiation dose in humans that would double the natural incidence of a genetic or somatic abnormality is not likely to be smaller than approximately 1 Sv (100 rem) [5]. The International Commission on Radiological Protection (ICRP) risk factors for hereditary effects are 0.01 Sv⁻¹ for all future generations for the whole population and 0.06 Sv⁻¹ for the population of adult workers.

The lifetime risk for a fatal cancer as determined by the ICRP is 0.05 Sv⁻¹ for the general population and 0.04 Sv⁻¹ for adult workers [4]. These are risk factors for cancer deaths, and not for cancer incidence. Some cancers have a relatively low mortality rate, so that the probabilities of cancer induction are generally higher by a factor of about 1.5. If we assume that the excess fatal cancer incidence is proportional to the radiation dose received, we can estimate the number of cancer deaths that might occur in an exposed group of people by multiplying the collective dose equivalent (person-Sv) by the cancer risk factor. For example, if a group of 100 000 people is exposed to 0.02 Sv, the estimated number of cancer deaths over the life span of the group would be 100 000 persons $\times$ 0.02 Sv $\times$ 0.05 Sv⁻¹ = 100 deaths. This number may be compared with about 25 000 deaths from cancer that would arise “naturally”. In practice, it would be impossible to distinguish cancer deaths that may have resulted from radiation exposure from those that would have otherwise occurred in the population.

Factors Affecting Degree of Hazard from Radioactive Compounds

Health risk from radioactive compounds can result from intake of the material, contact with the material, or being within the range of the radiation that the material gives off. The degree of health risk from a radioactive compound varies with the following factors.

The Concentration and Strength of the Radionuclide in the Material

Radionuclides can be found in trace quantities in materials that are encountered, or as purified sources or major constituents of materials. The activity of a radionuclide per unit weight of element present is called its *specific activity*. Specific activity can be expressed in units such as curies per gram or terabecquerel per gram. Specific activities of common radionuclides included in Table 1 range (in their pure forms) over almost 14 orders of magnitude, from 0.00000000405 for thorium-232 to 322 000 TBq g⁻¹ for sodium-24 (0.000000109 to 8 710 000 Ci g⁻¹ in traditional units).

The amount of material necessary to assemble 1 Ci of radioactivity can vary from a quantity too small to be seen (less than a microgram for sodium-24, for example) to tons of the material (more than 9 MT for thorium-232). The specific γ -ray dose constants presented in Table 1 illustrate how some radionuclides are sources of more intense radiation than others. These constants, which represent the approximate dose rate at a distance of 1 m from a γ radiation source for each megabecquerel of activity that it contains, vary by more than a factor of 100 000 from 0.000000001424 mSv h⁻¹ MBq⁻¹ for polonium-210 to 0.000524 mSv h⁻¹ MBq⁻¹ (1.8 rem h⁻¹ Ci⁻¹) for sodium-24.

The Type of Radiation That is Emitted

There are several more common forms of radiation that have enough energy to damage cells or other atoms. These “ionizing” radiations include α particles, β particles, and γ rays.

α Particles are relatively large subatomic fragments consisting of two protons and two neutrons that are ejected from the nucleus of some unstable atoms. They are the least penetrating form of radiation, as depicted in Figure 1, as they can be stopped by an inch or two of air or thin layers of light materials, such as a sheet of paper or the outer layer of one’s skin.

β Particles are subatomic particles (essentially electrons) that are ejected from the nucleus of some radioactive atoms. Over 7000 times smaller than α particles, β particles are more penetrating than α particles, but they are stopped by several feet of air. They are less ionizing and thus do less cellular

Figure 1 Penetrating abilities of the main types of radiation

damage, but can still present a substantial risk. Most β rays would be absorbed by one’s clothing, a few sheets of cardboard, or an acrylic sheet.

γ Rays are not particles, but rather electromagnetic radiations like the visible light from the sun and ultraviolet light, but with higher energies. γ Rays are essentially the same as X rays, but γ rays originate in the nucleus and X rays originate in the electron fields surrounding the nucleus. γ Rays are highly penetrating – it takes about 1 in. of solid steel to absorb 50% of them.

The Route by Which Exposure Occurs

Radioactive materials can appear as solids, powders, dusts, liquids, gases, vapors, or solutions. Radioactive compounds can enter the body by inhalation, ingestion, or absorption through the unbroken skin or through wounds. Unlike chemical toxins, radioactive materials can present health hazards even if a person does not touch the material or take any into the body. If a person is within the range of radiations that are emitted from the material, even if the material itself is well contained, exposure can occur as radiation is absorbed by body tissues in its path.

A source of α radiation kept outside your body is not a significant hazard. Radioactive material that emits α particles can pose a serious health threat when it is taken into the body. While α particles will not travel far into the body, they are “highly ionizing” and can do a lot of cellular damage along their short paths.

Direct exposure to β particles is a hazard, because emissions from strong sources can redden or even burn the skin. However, emissions from inhaled or ingested β -particle emitters are the greatest concern. β Particles released directly to living tissue can cause damage at the molecular level, which can disrupt cell

function. As they are much smaller and have less charge than α particles, β particles generally travel further into tissues. As a result, the cellular damage is more dispersed.

Both direct (external) and internal exposures to γ rays are of concern. γ Rays can travel much farther than α or β particles and have enough energy to pass entirely through the body, potentially exposing all organs. A large portion of γ radiation largely passes through the body without interacting with tissue. Most of the radiation dose received by the internal organs of the body from an external source would be from γ rays.

How the Material Behaves in the Human Body

The hazard from a radionuclide taken into the body depends on numerous factors, including its physical form, chemical form, solubility, where it is retained in the body, and how quickly the levels in body tissues decrease through radioactive decay and biological elimination. The particle sizes of a material determine whether it will make it into the lungs or whether it will be collected in the nasal passages or the upper respiratory tract. If a radioactive material is soluble in body fluids, it is called *transportable* and will enter the blood stream from the lungs or the digestive tract. It will normally deposit in various body organs at different levels depending on its physical and chemical properties, and will be eliminated *via* the urine and/or feces. If a radioactive material is not soluble in body fluids, it will typically be retained in the lungs for some period of time, with a fraction transported from the lungs by ciliary action leading to eventual elimination in the feces.

The time required for a radionuclide to lose 50% of its activity by decay is called its *radioactive (or physical) half-life* ($T_{1/2}$). While the amount present in the body decreases owing to radioactive decay, it also decreases owing to biological elimination. The biological half-life (T_b) is the time taken for the amount of a particular element in the body to decrease to half its initial value owing to elimination by biological processes alone. An effective half-life (T_{eff}), the time taken for the amount of a specified radionuclide in the body to decrease to half its initial value as a result of both radioactive decay and biological elimination, can be calculated as follows:

$$T_{\text{eff}} = \frac{(T_{1/2} \times T_b)}{(T_{1/2} + T_b)} \quad (1)$$

As can be seen in Table 1, a short biological half-life can result in a short effective half-life even when the physical half-life is very long in comparison (see ^{60}Co , ^{235}U , and ^{238}U).

Much research has been conducted on humans and animals to describe how radioactive materials are retained and transported in the human body and to describe the kinetics of retention and excretion. For many radionuclides, detailed mathematical models have been developed to support prediction and/or reconstruction of concentrations of radionuclides in the different body tissues over time so that doses to specific organs can be estimated and health risks evaluated. For example, models have been developed that represent in the following manner [4, 10, 11]:

- The respiratory system in four regions and 10 compartments, with compartmental fractions and removal halftime specified for three classes of retained material [Class D = minimum retention (halftime less than 10 days), Class W = moderate retention (10–100 days), and Class Y = avoid retention (greater than 100 days)] (see Figure 2).
- The gastrointestinal (GI) tract in four sections and five compartments, with mean residence times specified for each section, halftime specified for transport from one section to the next, and a half-time specified for transport of the radionuclide from the small intestine to the body fluids compartment. Data are provided for up to three different classes of material based on the fraction of ingested material that is transferred to the blood.
- The skeleton in six tissue types, with factors describing irradiation of cells near bone surfaces and red bone marrow from each tissue type, for radionuclides that bind to bone surfaces or are distributed uniformly through the bone volume.
- Clearance of radionuclides into organs and tissues after translocation from the GI tract or the respiratory tract into body fluids, with excretion also represented with specified halftime.

On the basis of these models, ingestion and inhalation dose coefficients are published, which allow one to estimate doses that will be received by 21 organs and a weighted total effective dose equivalent to age 70 following intakes at various ages [12].

Table 1 Data relevant to radiological hazard from selected radionuclides^(a)

Radionuclide	Key radiations ^(b)	Specific activity of isotope ^(c) (TBq g ⁻¹)	Specific γ -ray dose constant ^(d) (mSv h ⁻¹ at 1 m MBq ⁻¹)	Half-life		Important organ ^(e)

Figure 2 Mathematical model used to describe clearance of radionuclides from the respiratory system. The values for the removal half-time, T_{a-j} , and compartmental fractions, F_{a-j} , are given in the tabular portion of the figure for each of the three classes of retained materials. The values given for D_{N-P} , D_{T-B} , and D_P (left column) are the regional depositions for an aerosol with an activity median aerodynamic diameter (AMAD) of $1\ \mu\text{m}$. The schematic drawing identifies the various clearance pathways from compartments a-j in the four respiratory regions, N-P, T-B, P, and L. n.a.: not applicable [Reproduced from [10]. © Pergamon Press, 1979.]

The Chemical Toxicity of the Material

Radionuclides and compounds that contain chemical toxicity do not behave noticeably different chemically than the stable forms of the same elements or compounds. Compounds that exhibit chemical toxicity in their stable forms will retain that toxicity when they contain radioactive isotopes. In some cases, chemical toxicity becomes secondary in importance to radiological hazard, but that is not always the case. For example, uranium is used in various military, aviation, nuclear power, and nuclear weapon applications. As a heavy metal, uranium in soluble forms damages the kidneys. Natural uranium normally contains 99.27% uranium-238, 0.72% uranium-235, and 0.0057% uranium-234 [3]. For some uses, uranium is “enriched” so that its fissionable ^{235}U isotope is more abundant. For individuals exposed to airborne uranium that is relatively soluble in body fluids, the chemical toxicity of uranium is believed to be predominant over the radiological toxicity for ^{235}U enrichments below 7 to 20% [13].

Radon Risk

What are Hazardous Materials?

THOMAS E. WIDNER

Radon

Radon, or more properly, radon-222, is a colorless, odorless, inert gas, which arises from the radioactive decay of radium-226. Radon is found, at varying levels, in all indoor and outdoor environments. It can diffuse through cracks in foundations, can be transported in water, and can move into basements through sewer lines or drain pipes [1]. It is of interest to the risk analysis community because inhaling radon, or more accurately its decay products or “progeny”, can expose lung tissue to significant doses of ionizing radiation in the form of α particles, which may in turn cause lung cancer [2, 3]. The United States Environmental Protection Agency (USEPA) [4] has estimated that, in the United States, exposure to radon progeny causes between 15 400 and 21 800 excess lung-cancer cases each year (depending on the risk model selected), but acknowledges that the range of uncertainty is between 3000 and 33 000 cases per year. Even the lowest of these figures make radon the second leading cause of lung cancer after cigarette smoking (*see Environmental Tobacco Smoke*).

The 10-fold range given by EPA suggests substantial uncertainty in radon risk assessments. One major uncertainty is the radiation exposure term (often expressed in working level months (WLM)) that will result from exposure to a given level of radon progeny (measured in pico curies or pCi l^{-1} of air). This issue is of such complexity that it was considered in a National Research Council report [5]. Nonetheless, it remains a major uncertainty [6].

Another uncertainty is form of the dose–response function (*see Dose–Response Analysis*) that translates radon dose into lung-cancer risk. Recent risk assessments [3, 4] have used a relative risk model in which the effect of radon exposure is to multiply baseline risk, and it is generally accepted that radon exposure and cigarette smoking interact multiplicatively to increase lung-cancer risk. Thus the baseline lung-cancer risk in an exposed population is an important uncertainty in any radon risk assessment.

Uncertainty also arises because many of the excess lung cancers predicted necessarily result from very large populations exposed to very low levels of radon. Since much of our data for estimation of radon progeny risks comes from uranium miner cohorts, which have high radon exposure levels and many confounding factors like exposure to ore dust and

diesel exhaust, there is a question of how these data apply to low-level environmental exposures. However, two large recent meta-analyses of studies of residential radon exposure and lung-cancer risk [7, 8] suggest that risk estimates per unit dose are fairly comparable between miner and residential studies.

Lung-cancer risks from living in radon contaminated homes can be substantial. The USEPA [1] estimates that people living in homes at the “action level” of 4 pCi l^{-1} of air have a lifetime risk of about 6 in 100 (6%) if they are smokers and about 7 in 1000 (0.7%) if they are nonsmokers. Lifetime risk is approximately proportional to exposure level. That is, 8 pCi l^{-1} has about twice the risk of 4 pCi l^{-1} and 2 pCi l^{-1} has about half the risk of 4 pCi l^{-1} . Reducing radon risk is a matter of reducing radon exposure levels. EPA recommends that radon reduction be undertaken when levels exceed 4 pCi l^{-1} and should be considered when levels exceed 2 pCi l^{-1} . While risks at the lower level are still substantial compared with allowable risks from things like food additives (generally in the range of 10^{-5} – 10^{-6}) reducing levels much below 2 pCi l^{-1} is difficult because of the ubiquitous nature of radon.

Since a major route of infiltration is through foundation cracks, sealing cracks may substantially reduce levels. More aggressive reduction strategies focus on systems that use pipes and fans to suck radon out of the soil spaces beneath the foundation floor (often referred to as *subslab* ventilation), and in some areas houses are constructed to be “radon proof” in the sense that subslab ventilation is a built-in feature [1]. Exposure can also result from radon in drinking water but is much less common and is of concern primarily for homes using groundwater as their water supply source. If radon in drinking water is of concern, aeration can substantially reduce levels (*see Environmental Risk Assessment of Water Pollution*).

Radon Risk

MICHAEL E. GINEVAN

Radon Risk

Background

Radon is an inert gas, produced naturally from radium in the decay series of uranium (Figure 1). Radon decays with a half-life of 3.82 days into a series of solid, short-lived radioisotopes that collectively are referred to as radon daughters, progeny, or decay products.

Radon was the first environmental respiratory carcinogen identified, being linked to increased risk of lung cancer in underground miners in the early twentieth century, even before smoking was found to cause lung cancer. Many epidemiologic studies of underground miners of uranium and other ores have established exposure to radon daughters as a cause of lung cancer [1–3]. In the miners exposed to radon in past centuries, very high lung cancer risks were observed; these were lower for more recent workers but the recent epidemiological studies still show clear evidence of existing cancer risk [3]. Cigarette smoking and radon decay products synergistically influence lung cancer risk in a manner that is supra-additive but submultiplicative,^a placing smokers who are exposed to high levels of radon at extremely high risk for lung cancer [1, 3]. Beginning in the 1970s, radon was found to be ubiquitous in the air of homes, at high levels in some, and concern quickly arose as to the associated lung cancer risk to the general population.

Increasingly elegant experimental studies have documented the occurrence of permanent damage to a cell from just one hit by an α particle [3]. This experimental finding suggests that assuming a linear nonthreshold relationship between exposure and risk at the levels found not only in mines but also in indoors is biologically appropriate. In this same type of experimental system, a bystander mutagenic effect has been demonstrated; a hit to a cell affects cells adjacent to the cell damaged by a single α particle [4]. This effect may amplify the risks of radon exposure beyond those anticipated based on the construct that passage of an α particle through a cell damages only that cell.

For historic reasons, the concentration of radon progeny in underground mines is generally expressed in working levels (WLs): 1 WL is any combination of radon progeny in 1 l of air that ultimately releases

1.3×10^5 MeV of alpha energy during decay. In the United States, concentrations of radon are generally given as picocuries per liter (pCi l^{-1}), a unit for the rate of decay. Exposure to 1 WL for 170 h equals 1 working level month (WLM) of exposure, a unit developed to describe exposure sustained by miners during the average number of hours spent underground. In SI units, concentration is described as Becquerels per cubic meter with 1 Bq m^{-3} equivalent to 1 pCi l^{-1} ; exposure is in units of joules per hour per cubic meter with 1 WLM equivalent to $3.5 \times 10^{-3} \text{ J h}^{-1} \text{ m}^{-3}$.

Radon and Lung Cancer Risk

As the biologic basis of respiratory carcinogenesis was understood and the lung dosimetry of radon and its short-lived progeny was described, it was recognized that α -particle emissions from inhaled radon progeny, not from radon itself, caused lung cancer in radon-exposed miners [3]. Two of those decay products, polonium-218 and polonium-214, emit α particles, which are high-energy and high-mass particles consisting of two protons and two neutrons that are very damaging to tissue. The energy of these particles is invariant with concentration of radon progeny so that the potential for passage of alpha particles to damage target cells is the same at high and low concentrations. When the alpha emissions take place within the lung as inhaled radon progeny decay, the DNA of cells lining the airways may be damaged and lung cancer may ultimately result. Animal studies demonstrated that radon alone through its progeny could induce cancer in the respiratory tract [1].

The relationship between radon progeny and lung cancer risk has been investigated in follow-up (cohort) studies (*see Cohort Studies*) of mining populations, including not only uranium miners but also miners of other types of ores who were exposed to radon either from the ore itself or from the radon dissolved in mine water. Those cohort studies with exposure estimates for the miners have shown that the risk for lung cancer increases proportionally with the cumulative exposure to radon progeny. These 11 studies were included in a pooled analysis reported by Lubin *et al.* [2, 3, 5] and extended by the Biological Effects of Ionizing Radiation (BEIR VI) Committee VI [3]. Although the individual cohort

Figure 1 Uranium decay chain

studies differ somewhat in the nature of the mining populations and in their methods, and not all include detailed smoking histories from all miners, the crude estimates of excess relative risk (ERR) per WLM of radon progeny exposure were reasonably close. As anticipated from the presumed mechanism of carcinogenesis, all of the studies documented increasing risk with increasing exposure without any indication of a threshold below which risk was not manifest.

The pooled analysis showed that the risk varied with time since exposure and the rate at which cumulative exposure was achieved, and was also modified by attained age and smoking. There is evidence for an inverse dose-rate effect or protraction enhancement, so that miners who were exposed at low concentrations over long periods of time have a higher risk than miners receiving the same total exposure over shorter periods. Risk also dropped as time since exposure lengthened and independently as attained age increased. The pooled analyses indicated a synergistic interaction between smoking and radon progeny. The age at which a miner is first exposed to radon does not appear to have a consistent effect on

risk overall, but the epidemiological data are limited at younger ages.

An elevated risk for lung cancer has also been shown in miners who have never smoked cigarettes. A follow-up study of 516 white nonsmoking miners from the Colorado Plateau cohort showed 14 lung cancer deaths with only 1.1 expected, based on the never-smokers in the study of US veterans [6]. Native American miners in the Colorado Plateau cohort, mostly Navajos, were almost all nonsmokers or very light smokers; a follow-up study of 757 members of this group identified 34 deaths from lung cancer when only 10.2 were expected [standardized mortality ratio (SMR) 3.3, 95% confidence interval (CI) 2.3–4.6], confirming an earlier case–control study of lung cancer in Navajo men [7]. A pooled analysis of the 2798 never-smoking miners in the 11 miner groups found that the estimated ERR/WLM for nonsmokers (0.0103, 95% CI 0.002–0.057) was almost three times that of smokers (0.0034, 95% CI 0.001–0.015), consistent with the submultiplicative interaction between smoking and radon in the full data set [2].

Radon and Indoor Environments

As information on air quality in indoor environments accumulated during the 1970s and 1980s, it became clear that radon and its decay products that are invariably present in indoor environments and in some dwellings may reach unacceptably high concentrations, equivalent to those in mines. In fact, radon is the greatest source of radiation exposure in the United States from natural background radiation [8]. Radon primarily enters homes and other buildings as soil gas is drawn in by the pressure gradient between the structure and the ground beneath. An extensive body of literature now addresses the risks of indoor radon [3, 9, 10]. The epidemiologic studies of miners of uranium and other ores have been the principal basis for estimating the risks of indoor radon, and the epidemiologic data have been extensively analyzed to develop risk models. More recent findings from case-control studies

of indoor radon and lung cancer in the general population have been reported and their findings pooled to enhance the precision of risk estimates. These studies compare radon concentrations at homes where persons with lung cancer lived with concentrations in homes of similar people who do not have lung cancer.

In response to the need for information on risks from indoor exposure, epidemiological studies directed at lung cancer in the general population were initiated in the 1970s and 1980s. The first wave of studies was largely ecological in design and provided mixed findings because of inherent flaws of this approach [8]. By the mid- to late-1980s, many case-control studies of more sophisticated design with larger sample sizes were undertaken. The findings, although having the inherent limitation of exposure measurement error, generally support the carcinogenicity of radon exposure in homes and are consistent quantitatively with expectations of risk

Table 1 Estimated number of lung cancer deaths in the United States in 1995 attributable to indoor residential radon progeny exposure^{(a)(b)}

Smoking status	Number of lung cancer deaths	Number of lung cancer deaths attributable to radon progeny exposure			
		Exposure-age-concentration model		Exposure-age-duration model	
Males^(c)					
Total	95 400	13 000 ^(d)	12 500 ^(e)	9200 ^(d)	8800 ^(e)
Ever-smokers	90 600	12 300	11 300	8700	7900
Never-smokers	4800	700	1200	500	900
Females^(c)					
Total	62 000	9300	9300	6600	6600

Ever-smokers	146 400	20 600	18 900	14 600	13 300
Never-smokers	11 000	1700	2900	1200	2100

^(a) Reproduced from [11]. US Government Printing Office, 1992

^(b) National Research Council (NRC), Committee on Health Risks of Exposure to Radon, Board on Radiation Effects Research, and Commission on Life Sciences. Health Effects of Exposure to Radon (BEIR VI). 1999. Washington, D.C., National Academy Press

^(c) Assuming that 95% of all lung cancers among males occur among ever-smokers, and that 90% of all lung cancers among females occur among ever-smokers. Percentages of ever-smokers in the population were 58 and 42% for males and females, respectively

^(d) Estimates based on applying same risk model to ever-smokers and never-smokers, implying a joint multiplicative relationship for radon progeny exposure and smoking

^(e) Estimates based on applying a smoking adjustment to the risk models, multiplying the base-line ERR/WLM by 0.9 for ever-smokers and by 2 for never-smokers, the committee's preferred approach

based on downward extrapolation of models based on the miner data.

In 2005, the results of pooled analyses of data from North America [9] and from Europe [10] were reported. The North American analysis included data from seven studies with 3662 cases and 4966 controls. The risk of lung cancer was estimated to increase by 11% (95% CI 0–28%) per 100 Bqm⁻³ increment in the concentration at which exposure occurs in a home. The estimate from the pooling of 13 European studies involving 7148 cases and 14 208 controls was similar; an increment of 8% (95% CI 3–16%) per 100 Bqm⁻³ increase in home concentration was estimated.

The burden of lung cancer associated with indoor radon has been estimated by using the distribution of indoor radon concentrations from surveys and the exposure–response relationship estimated from the miner studies. The assumptions made by the Environmental Protection Agency and the BEIR IV and VI committees of the National Research Council lead to estimates that approximately 15 000–20 000 lung cancer deaths per year in the United States are caused by radon (Table 1) [11]. A substantial proportion of these premature deaths could be avoided through the use of testing programs that identify homes with unacceptably high concentrations.

End Notes

^a. That is, the combined effect exceeds that expected from adding the individual effects of radon decay products and of smoking but is less than the expected value based on multiplying the effects of radon decay products and smoking.

Randomized Controlled Trials

In the medical sciences, the ideal experiment is the randomized controlled clinical trial (RCT) in which the subject or patient is randomized to treatment with an experimental agent or control (either placebo or other active treatment), in a double-blind manner. The RCT is the “gold standard” in medical research to establish the efficacy of a new treatment or intervention. The benefits of such an experiment are that any observed differences between the two groups (or more groups) with respect to the outcome can be attributed to the treatment and are without bias. That is, confounding is controlled and selection bias is removed since neither the subject nor the investigator chooses the intervention [1].

In this article, we review the issues in the design, conduct, analysis, and interpretation of a randomized clinical trial.

Design Considerations

The concepts of the RCT are applicable to any clinical trial from phase I to phase III and beyond (see phase I–III trials). Most of our remarks here will apply to phase III comparative efficacy trials, but can be generalized also to earlier phase clinical trials.

Early Phase Trials

Although early phase trials are generally not randomized, the randomization framework can be useful to permit the direct comparison of toxicities and adverse events for the new treatment or intervention with toxicities and adverse events in a control group. In such cases, randomization would minimize the risk of attributing adverse events that might be due to the underlying condition from those that might be attributable to the intervention. The use of the RCT paradigm in such trials would reduce the risk of incorrectly attributing safety issues to a new drug early in the development process. Similarly, phase II studies are often uncontrolled, but in many instances randomized designs can be implemented to eliminate the selection bias associated with treatment assignment. In such cases, formal comparisons of the treatment

and control arms will be of limited utility due to low power to detect differences. However, some phase II trials can be conducted in diseases such as hypertension using RCT designs for preliminary dose finding with results to be confirmed in definitive phase III trials.

Example of Randomized Phase III Trial

The classic example of a large randomized comparative efficacy trial (phase III) is the Salk vaccine trial that was conducted in 1954. Over one million children participated in the trial. This trial was conducted to assess the effectiveness of the Salk vaccine to provide protection against paralysis or death from poliomyelitis as described in detail by Meier [2]. The ideal design is as a randomized controlled trial. Since there was considerable reluctance to allow children to receive placebo injections, an observed control study was designed with children in grade 2 to receive vaccinations and children in grades 1 and 3 to be observed for the occurrence of polio. After much debate, some states agreed to participate in a randomized component. In the RCT, 750 000 children were randomly assigned to injections either with the Salk vaccine or with a placebo salt solution. The trial was double blind, that is, neither the children nor the diagnosing physicians were aware of who had received the Salk vaccine or the placebo. Patients and/or their physicians participating in the study are often blinded to the treatment assignment to reduce the likelihood of treatment-related bias due to the knowledge of treatment assignment (*see* **Blinding**). The Salk vaccine trial was conducted in a relatively short period of time, and the endpoints were observed within this relatively short time period. The results obtained for the RCT component of the trial were unequivocal and were supported by the observed control component which, although supportive, would not have provided compelling evidence that the vaccine was effective.

Key Design Issues

At the design stage of a randomized controlled trial, the investigators need to carefully consider several key issues that include the choice of the treatment and control regimens including the methods of treatment delivery; the types of patients and severity of disease to be studied; the level of blinding; the use

of a parallel group design or some alternative (e.g., cross-over trial); the need for stratification; choice of a single or multicenter trial; the length of the treatment and/or observation period; the unit of analysis (e.g., patient or eye within patient); the outcomes (short term, long term, surrogates); the measurements of these outcomes including measurement error; and the size of a meaningful treatment effect (statistical significance *versus* clinical significance). Special issues that relate to the use of surrogate endpoints that should correlate with the long-term outcome of interest should also be considered [3, 4]. Designs of definitive randomized controlled trials of new drugs or devices also need to consider the regulatory requirements for the approval of such drugs or devices to minimize risks of failing to meet the overall objective of approval of a new drug or device for use [5, 6].

Blinding and Randomization. In the planning stages of a clinical trial, it is prudent to consider the use of a blinded RCT as the first type of design. Careful consideration should be given to the choice of the treatment regimen or intervention to be studied as well as to the selection of the control treatment or intervention. Sometimes the nature of a study precludes blinding of participants and/or health care providers (Friedman *et al.* [7] and Redmond and Colton [8]; see **Blinding**). However, even when the study participants and those administering treatment cannot be blinded, blinding of outcome assessment could still be possible and helps prevent detection bias [9, 10].

If blinding is not feasible, randomization should still be attempted, and the use of an uncontrolled (nonrandomized) design should be justified.

Choice of Study Population. The study population is defined by the specification of criteria for entry into the study. These criteria must be carefully developed in advance to allow the population under study to be adequately characterized and to facilitate the replication of the results of the study. The selection of the patient population ranges from the consideration of a homogeneous, well-defined population to a heterogeneous population that allows easier recruitment and permits broader generalization of study results. The choice of the population for study depends on the objectives of the study and the ability to detect a meaningful benefit in a well-defined

homogeneous patient population compared with the dilution of potential effects (depending upon mechanism of action) in a more heterogeneous population. For example, a treatment may work well in a relatively small proportion of the population. In such a case, if this subgroup is a relatively small group in the total study population, the study will fail to detect an overall effect.

Study Objectives and Sample Size. Sample size considerations for the RCT depend upon the trial objectives as well as the outcome measurement. The trial can be designed to compare a new treatment or regimen against a standard treatment or placebo or observation with the expectation that the new treatment will be better than the standard treatment or the placebo regimen. Or, the trial may be designed to assess whether a new treatment or intervention is no worse than the standard treatment or intervention by some specified margin. The required sample size for the trial depends upon the absolute or relative difference in the measurement of the primary outcome between the treatment and control groups that can be a binary response rate, a continuous measurement of change from baseline, or a failure or survival time (see phase III trial section for discussion of sample size considerations and [11–13] for methods).

In the design of a randomized controlled trial, the risks of committing either of the two common types of errors in hypothesis testing–based trial designs need to be controlled. A type I error is made if the study leads to a false rejection of the null hypothesis, H_0 , and a type II error is made if the study fails to establish the alternative hypothesis H_1 when it is indeed true. The probabilities of type I and type II errors, often denoted as α and β , respectively, should be minimized. The statistical power of a test is defined as the probability $1 - \beta$.

Single-Center Trials. The simplest RCT is one that is carried out at a single institution or center with patients treated uniformly according to a well-defined protocol under the direction of the same investigator. The patients (units of observation) generally constitute a fairly homogeneous group with respect to demographic and prognostic characteristics. The protocol defines the patient population under study, the criteria for entry, adequacy of design to answer the question under study, the randomization and blinding

schema, and procedures for implementing all aspects of protocol compliance, data quality and integrity, and patient outcomes.

Statistical theory assumes that there is a “population” of subjects who meet an agreed definition of eligibility, but, in practice, patients treated in a study are those who come to the attention of the investigator, meet the criteria, and agree to be randomized. Unfortunately, although the notion of randomization allows us to make inferences about the treatment for this group of patients, randomization within the study does not offer any help in generalizing the results beyond the limited population under study at that center. Therefore, it is important to measure and report characteristics of both patient and center that may provide information regarding generalizability. Furthermore, there may be some characteristic, possibly unknown, or some specific skills associated with the single center that may be uniquely related to the observed treatment effect at that center. Such effects can only be identified if the experiment is repeated at other centers.

Frequently, the number of patients available at a single center is inadequate to provide sufficient data to answer the question under study. Therefore, multiple centers and, hence, multicenter trials are needed to obtain the required number of patients in a timely manner.

Multicenter Trials. The choice of a multicenter trial, rather than multiple single-center studies, is to enable prospective planning for the combination of data from multiple centers [14, 15]. The multicenter trial requires that a common protocol be used at each center and that procedures are in place to ensure consistency in the application of the protocol and all measurements across centers, including patient inclusion/exclusion criteria, administration of randomization and stratification schema, definitions of treatment regimens/outcomes, prognostic factors, methods of patient classification, methods for outcome assessment, definition of protocol compliance, study conduct, and operational definitions. The protocol and investigator meetings, as well as procedures for the conduct and the monitoring of a multicenter trial, go a long way toward ensuring that the results of the trial will be interpretable and generalizable. The measurement of treatment effect is agreed on by all investigators, and the methods for combining the

results across individual centers are, ideally, specified as part of the protocol.

Adaptive Designs

While many randomized controlled trials are designed with a fixed sample size that is specified at the start of the study, new strategies for randomization have developed that include adaptive randomization procedures which allow new patients to be randomized on the basis of the results obtained prior to patient entry (e.g., Zelen’s play the winner rule [16]). The use of interactive voice recognition and computer-based randomization systems has enabled dynamic balancing of subjects at randomization to maintain balance among several stratification variables. These procedures are particularly useful in multicenter trials with small center sizes where balancing within center on multiple factors is not feasible.

Group Sequential Trial Designs

In sequential trials, enrollment and observation continue until a specified stopping boundary is crossed. Inference about the treatment effect in sequential designs incorporates the fact that the stopping time of the trial is random in order to avoid bias. Methods for the design and analysis of phase III trials using group sequential procedures with interim analysis are described in Proschan *et al.* [17]. The two most common approaches are (a) O’Brien–Fleming boundaries that permit early stopping for success with stringent α -level requirements and maintain almost all of the α level for the final planned look [18] and (b) Pocock boundaries that divide the α level equally among the planned looks making it easier to stop the trial early [19]. These approaches fall under the class of Lan–DeMets spending functions with different parameterizations [20].

Analysis Issues

The analysis of any randomized clinical trial follows from the design of the trial and is based on the comparison of the specified treatment effect in the new treatment group *versus* the treatment effect in the standard treatment or placebo group. The magnitude of efficacy differences among treatment groups can

be evaluated using appropriate measures such as the difference in response rates, means, hazard rates (*see Hazard and Hazard Ratio*), and median survival times along with the corresponding confidence intervals [7, 11–13].

Stratification in the randomization of patients to treatment groups is also incorporated into the analysis with stratification factors used as covariates in the appropriate models. We note that in multicenter trials, center effects are considered as fixed or random effects [14]. However, if the center size or class size for a level of stratification variable is relatively small, power can be reduced when the stratification is incorporated into the primary analysis.

When repeated measurements of response and/or covariates are taken on subjects over the time course of the trial, analysis of the trial data should incorporate the positive correlations among the measurements on the same subject (*see Repeated Measures Analyses*).

Intention to treat analyses that include all randomized patients regardless of compliance to protocol or missing data are generally preferred to obtain an unbiased test of the treatment effect based on the randomization (*see Intent-to-Treat Principle*). Lack of compliance and missing data that may be related to the treatment under study can lead to bias in the estimated treatment effect (*see Compliance with Treatment Allocation*). Harrington [1] discusses some of these choices for analysis and implications for interpretation of results.

Discussion

This article provides a brief overview of many of the statistical issues in the design and analysis of RCTs that can impact the results and interpretation of the trial. There are many excellent references that provide detailed discussions of these issues: Harrington [1] for a brief tutorial and reference books by Piantadosi [13], Friedman *et al.* [7], Pocock [19], Fleiss *et al.* [12], Chow and Liu [11] among others.

New trial designs and methods are focused on reducing the numbers of patients enrolled in randomized trials and on shortening the time to decision making. For example, Bayesian methods (*see Bayesian Statistics in Quantitative Risk Assessment*) are now being used to obtain regulatory approval for

new drugs based on randomized clinical trials. Berry [21] provides a recent review of these Bayesian approaches and recent experience in practice.

Recurrent Event Data

Byar [1] presents a medical study of patients who had bladder tumors upon entry. The initial tumors were removed using surgical techniques and patients were classified according to treatment (group 1 = placebo, group 2 = thiotepa, group 3 = pyridoxine). Throughout the study, patients experienced multiple recurrences of the tumors. Each time there was a recurrence, the tumors were again removed using a surgical intervention. The times (in months) of the tumor recurrences are presented in Wei *et al.* [2]. One aspect the researchers were interested in was the effectiveness of thiotepa based on the recurrence times of the tumors.

In the aforementioned study, the patients experienced an event of interest multiple times, that being the recurrence of tumors. The resulting data is termed *recurrent event data*. Recurrent events are ordered and each event of interest is treated as being of the same nature. Such data is considered a special case of multivariate lifetime data (*see* **Dependent Insurance Risks; Lifetime Models and Risk Assessment**).

Recurrent event data occurs in a wide array of disciplines. Examples in survival analysis (*see* **Mathematics of Risk and Reliability: A Select History**) include the reoccurrence of asthma attacks, seizures, tumors, and infections. In reliability, the events could be the breakdown of brake systems in city buses, bugs that occur in software programs, and the repeated fixing of aircraft. In the social and political sciences, examples include the recidivism rate of criminals, absenteeism of employees, and the occurrence of geographical conflicts.

There are several issues to consider when analyzing recurrent event data. These include the correlation of the event-of-interest calendar times within units, the effects of interventions that are applied to bring units back to “operational condition”, the impact of accumulating event occurrences on a unit, and the effects of possibly time-dependent covariates.

Many approaches for studying recurrent event data have been proposed in the literature. These include parametric, nonparametric, and semiparametric models both in the classical and Bayesian framework. Treatment of many of these approaches can be found in the books of Hougaard [3], Kalbfleisch and Prentice [4], Rigdon and Basu [5], Therneau

and Grambsch [6], Nelson [7], and Ascher and Feingold [8].

Many models are intensity based. To incorporate the correlation amongst event-of-interest calendar times researchers use a variety of strategies in these intensity-based models (*see* **Default Correlation; Default Risk**). These include using time-dependent covariates, the use of effective age (EA) processes, and the inclusion of random effect components referred to as *frailties*. Other authors do not specify any structure for the correlation. Instead, they provide an appropriate adjusted estimate for the variance–covariance matrix. Models often differ in their definition of the at-risk process to reflect the nature of recurrent events. The use of models based on mean rate functions is given as an alternative to those that are intensity based. They impose fewer assumptions and are presented as having better interpretability.

This article describes the models of Peña and Hollander [9] (EA model), Prentice, Williams, and Peterson [10] (PWP model), Wei, Lin, and Weissfeld [2] (WLW model), and those studied by Lin, Wei, Yang, and Ying [11] (LWYY model).

The article gives the mathematical setup and describes several classes of models used to analyze recurrent event data in the section titled “General Classes of Models”. It examines the bladder tumor data of Byar [1] in the section titled “Illustrative Example”. Some conclusions and other topics to be considered when analyzing recurrent event data are presented in the section titled “Concluding Remarks”.

General Classes of Models

We consider a study with n units. Each i th unit is observed over a time interval $[0, \tau_i]$, where τ_i is a right censoring (*see* **Imprecise Reliability**) random variable. We assume that the censoring random variable is independent and noninformative (*see* Andersen *et al.* [12, p. 138 and 171]). For each i th unit, we observe events of interest at calendar times $0 \equiv S_{i,0} < S_{i,1} < \dots$. Associated with these calendar times are the gaptimes, $T_{i,k} = S_{i,k} - S_{i,k-1}$. The counting process, $N_i(s)$ is the number of observed events of interest over the time interval $[0, s]$.

For a continuous distribution function $F(s)$ with associated density function $f(s)$, define the hazard rate function (*see* **Mathematical Models of Credit**

Risk; Repair, Inspection, and Replacement Models; Reliability Data) $\lambda(s) = f(s)/(1 - F(s))$, with the convention that $0/0 = 0$. A heuristic interpretation is

$$\lambda(s) ds \approx \text{probability of an event occurring within the next instant of time} \quad (1)$$

The cumulative hazard function is defined as $\Lambda(s) = \int_0^s \lambda(w) dw = -\log(1 - F(s))$. The survivor function (see **Hazard and Hazard Ratio**) is defined as $\bar{F}(s) = 1 - F(s)$.

EA Model

A general class of models for analyzing recurrent event data is given by Peña and Hollander [9]. The class of models assumes the intensity process that has the form

$$\lambda_i(s) = Y_i(s)Z_i\lambda_0(\mathcal{E}_i(s))\rho(N_i(s-); \alpha)\psi(\beta^t X_i(s)) \quad (2)$$

where $Y_i(s) = I(\tau_i \geq s)$ is the at-risk process. It is of interest to note that the value of $Y(\cdot)$ remains one as events of interest occur.

The baseline hazard function is perturbed by the observable and predictable EA process $\{\mathcal{E}_i(s)|0 \leq s \leq \tau_i\}$. Figure 1 represents the EA process for unit 1 in a study. The EA process between $S_{1,0}$ and $S_{1,2}$ is $\mathcal{E}_i(s) = s$. At the time of the first event of interest, $S_{1,1}$ the unit is “minimally repaired”. A “perfect repair” then occurs to the unit at the time of the second event of interest, $S_{1,2}$. The EA process then is represented by a nonlinear function between $S_{1,2}$ and $S_{1,3}$ and also between $S_{1,3}$ and $S_{1,4}$. After the third event of interest, a repair is performed that is between minimal and perfect. The time of the fourth event of interest, $S_{1,4}$ is not observed and is censored at τ_1 .

The frailty (see **Risk Classification/Life**) Z_i allows the researcher to model heterogeneity among the units and acts as a random-effect component. The $\rho(\cdot; \alpha)$ function permits accounting of the weakening or strengthening impact from the accumulating event occurrences. The function $\psi(\cdot) : \mathbb{R} \mapsto \mathbb{R}^+$ links the effects of concomitant variables to the intensity rate.

The generality of this class of models was demonstrated in Peña and Hollander [9] where they showed that many existing models in reliability and survival analysis are subsumed by this class. For instance, it includes models by Andersen and Gill

Figure 1 Graph of effective age versus calendar time for unit 1

[13], Prentice *et al.* [10], Kijima [14], Lawless [15], Aalen and Husebye [16], Dorado *et al.* [17], and Last and Szekli [18].

When $\mathcal{E}_i(s) = s$, $Z_i = 1$, and $\rho(N_i(s-); \alpha) = 1$, the EA general class of models reduces to the model of Andersen and Gill (AG) model [13]. The correlation amongst the calendar times is incorporated in the model using time-varying covariates. Therneau and Grambsch [6] discuss implementation of the AG model using SAS and Splus. They advocate a jackknife estimate of the variance-covariance matrix to adjust for the correlation in the calendar times within units.

The general class of models is studied under a fully parametric specification for the baseline hazard rate function by Stocker and Peña [19]. A treatment of the semiparametric model is given by Peña *et al.* [20]. In both papers, the authors use a reformulation of the EA model that incorporates both calendar and gaptime timescales. This reformulation yields a process that can be viewed as a generalized at-risk process. Stocker and Peña [19] demonstrate how this reformulation viewed in terms of gaptime is useful in verifying regularity conditions needed to prove asymptotic properties of parameter estimates. Peña *et al.* [20] use the reformulation to construct a methods of moments estimator for $\Lambda(\cdot|\alpha, \beta)$ in the gaptime timescale. More details can be found in the above references [19, 20].

PWP Model

Prentice *et al.* [10] model recurrent event data utilizing event-specific stratum. A unit at time s is in the k th stratum if it has experienced $k - 1$ events of interest. The use of stratum creates a definition of

the at-risk process that is different from that of the EA class of models. The PWP model has an at-risk process that changes as units experience events of interest, while the at-risk process for the EA class of models remains one. Prentice *et al.* [10] suggest using semiparametric hazard rate functions of the form

$$\lambda(s) = \lambda_{0k}(s) \exp(\beta_k^t X(s)) \quad (3)$$

and

$$\lambda(s) = \lambda_{0k}(s - S_{i,N_i(s)}) \exp(\beta_k^t X(s)) \quad (4)$$

PWP models that use hazard rates of the form given in equations (3) and (4) will be referred to respectively as *PWP calendar time* and *PWP gaptime*. Note the index k allows the hazard rate functions and regression parameters to differ from stratum to stratum. Partial likelihood functions can be formed for either choice of hazard rate function. Maximization of these likelihood functions gives estimates of the regression parameters. Large sample theory can be employed to construct inference procedures. Implementation of this model using SAS and Splus is given in Therneau and Grambsch [6].

WLW Model

Wei *et al.* [2] presented semiparametric methods to analyze multivariate lifetime data. They model each event of interest with a Cox proportional hazards model (see **Comparative Risk Assessment; Competing Risks**). This marginal modeling does not specify a form for the correlation between calendar times within units. This differs from the EA and PWP class of models that use EA processes.

For the k th event of interest ($k = 1, 2, \dots, K$) of the i th subject the intensity process is

$$\lambda_{ik}(s) = Y_{ik}(s) \lambda_{0k}(s) \exp(\beta_k^t \mathbf{X}_{ik}(s)) \quad (5)$$

where $Y_{ik}(s) = I(S_{i,k-1} \leq s < S_{i,k})$ is the at-risk process for the i th subject with respect to the k th event of interest. β_k is a q -dimensional event-specific parameter with associated covariate process $\mathbf{X}_{ik}(s)$. The unknown parameter estimates are found by maximizing the event-specific Cox partial likelihoods. Wei *et al.* [2] provide large sample theory and give an estimate of the variance-covariance matrix. Therneau and Grambsch [6] discuss implementation of these models using SAS and Splus.

Mean Rate Models

Many modeling approaches of recurrent event data have focused on the intensity-based methods of Andersen and Gill [13]. Denote $dN(s) = N(s-) - N((s + \Delta s)-)$ and $\mathcal{H}_{s-}$ as the history of the process just before time s ($\mathcal{H}_s$ is called a *filtration*). These models impose a nonhomogeneous Poisson process (see **Product Risk Management; Testing and Warranties; Reliability Growth Testing**) structure on $dN(s)$, where the intensity function is given by

$$E(dN(s)|\mathcal{H}_{s-}) = \lambda(s) ds \quad (6)$$

This assumption is seen by many authors as restrictive and interpretability of $\lambda(\cdot)$ maybe difficult for practitioners. In the AG model (see [13]), the correlation between event calendar times is modeled using time-dependent covariates. This assumption may be wrong and there is no way to check whether it is correct. Many authors have advocated the use of the mean rate function, denoted by $\mu(s|\mathbf{X}(s))$. It is defined as

$$\mu(s|\mathbf{X}(s)) = \int_0^s \exp(\beta^t \mathbf{X}(w)) d\mu_0(w) \quad (7)$$

or heuristically as

$$\begin{aligned} d\mu(s|\mathbf{X}(s)) &= E(dN(s)|\mathbf{X}(s)) \\ &= \exp(\beta^t \mathbf{X}(s)) d\mu_0(s) \end{aligned} \quad (8)$$

where $\mu_0(s)$ is an unknown continuous function. If $\mathbf{X}(s)$ consists only of external covariates (see Kalbfleisch and Prentice [4, p. 123]) then $\mu(s|\mathbf{X}(s))$ is interpreted as the mean function of recurrent events. The resulting model is termed *proportional rates model*. If the covariate process is time invariant then the model is termed the *proportional means model*. Lin *et al.* [11] study these models. They give appropriate score functions for estimation of $\mu_0(\cdot)$ and β . Asymptotics are proven using modern empirical process theory as outlined in van der Vaart and Wellner [21]. Appropriate inferential procedures for $\mu(s|\mathbf{X}(s))$ and β are given. They also provide graphical and numerical techniques for model checking.

Illustrative Example

The bladder tumor data of Byar [1] were modeled with those models described in the section titled

“General Classes of Models”. Only the 85 patients who were either from the placebo or thiotepa treatment groups were considered. A maximum of four recurrences per patient were recorded. The data is given in Wei *et al.* [2]. The covariates for each patient are a treatment indicator (placebo or thiotepa), the size in centimeters of the largest initial tumor, and the number of initial tumors. Our main interest was comparing the placebo versus thiotepa groups. The models used were AG, EA, WLW, PWP calendar time, PWP gaptime, and the mean rate models.

Uncommon and common regression coefficients were incorporated into the WLW and PWP models. Therefore, equations (3)–(5) have link functions of the form $\exp(\beta_k' X)$ and $\exp(\beta' X)$ resulting in six different models. For the EA model, $\rho(k; \alpha) = \alpha^k$ was used. For demonstration purposes, two choices were examined for the EA process: $\mathcal{E}_i(s) = s$ (minimal repair) and $\mathcal{E}_i(s) = s - S_{i, N_i(s-)}$ (perfect repair). It was assumed $Z_i \sim \text{gamma}(\eta, \eta)$ ($E(Z_i) = 1$ and $\text{Var}(Z_i) = 1/\eta$) for $i = 1, 2, \dots, 85$. This choice is common in frailty models. The results of all the analyzes are found in Tables 1–5.

Tables 1–3 contain the parameter estimates, standard errors, test statistics, and p values associated with the treatment covariate (placebo or thiotepa) for the WLW, PWP calendar time, and PWP gaptime

Table 1 Table of parameter estimates, standard errors, test statistics, and p values for the WLW model using common regression coefficients. The parameter Trt corresponds to the treatment covariate for each marginal model (1, 2, 3, and 4)

Variable	Estimate	Standard error	Test statistic	p value
Trt 1	−0.52	0.31	2.83	0.0923
Trt 2	−0.62	0.36	2.90	0.0887
Trt 3	−0.70	0.42	2.84	0.0918
Trt 4	−0.65	0.50	1.77	0.1839

Table 2 Table of parameter estimates, standard errors, test statistics, and p values for the PWP calendar time model. The parameter Trt corresponds to the treatment covariate for each stratum (1, 2, 3, and 4)

Variable	Estimate	Standard error	Test statistic	p value
Trt 1	−0.52	0.32	2.69	0.1012
Trt 2	−0.46	0.41	1.28	0.2581
Trt 3	0.12	0.67	0.03	0.8617
Trt 4	−0.04	0.79	0.00	0.9592

Table 3 Table of parameter estimates, standard errors, test statistics, and p values for the PWP gaptime model. The parameter Trt corresponds to the treatment covariate for each stratum (1, 2, 3, and 4)

Variable	Estimate	Standard error	Test statistic	p value
Trt 1	−0.52	0.32	2.69	0.1012
Trt 2	−0.26	0.41	0.41	0.5224
Trt 3	0.22	0.55	0.16	0.6873
Trt 4	−0.20	0.64	0.09	0.7613

models when uncommon regression coefficients were used. The test statistics are χ^2 distributed with one degree of freedom under the null hypothesis. For all three models, the test statistics are not statistically significant.

Table 4 contains the parameter estimates and standard errors (in parentheses) for common regression coefficients for the WLW and PWP calendar time models. Also included in Table 4 are the parameter estimates and standard errors for the AG and mean rate models. Table 5 contains the parameter estimates and standard errors (in parentheses) for the PWP gaptime and EA models. In Tables 4 and 5, the parameter vector $\beta = (\beta_1, \beta_2, \beta_3)^t$ corresponds to the covariates: treatment group, size of the initial tumors, and

Table 4 Table of parameter estimates and corresponding standard errors for the AG, mean rate, WLW, and PWP calendar time models

Parameter	AG	Mean rate	WLW	PWP calendar
α	NA	NA	NA	NA
η	NA	NA	NA	NA
β_1	−0.47 (0.20)	−0.47 (0.26)	−0.58 (0.20)	−0.33 (0.21)
β_2	−0.04 (0.07)	−0.04 (0.08)	−0.05 (0.07)	−0.01 (0.07)
β_3	0.18 (0.05)	0.18 (0.06)	0.21 (0.05)	0.12 (0.05)

Table 5 Table of parameter estimates and corresponding standard errors for the PWP gaptime and EA models. The effective age processes used in the EA models are perfect repair (EA perfect) and minimal repair (EA minimal)

Parameter	PWP gap	EA perfect	EA minimal
α	NA	0.98 (0.07)	0.79 (0.13)
η	NA	∞	0.97
β_1	-0.28 (0.21)	-0.32 (0.21)	-0.57 (0.36)
β_2	0.01 (0.07)	-0.02 (0.07)	-0.03 (0.10)
β_3	0.16 (0.05)	0.14 (0.05)	0.22 (0.10)

number of initial tumors. The results for the EA models are also found in Peña *et al.* [20]. The parameter estimates obtained using the AG and mean rate models are exactly the same. These estimates are found by solving the same score equations. The standard errors are computed differently. This results in a significantly larger standard error for the treatment indicator parameter β_1 for the mean rate model. One degree of freedom χ^2 tests indicate that thiotepa is effective at the 0.05 significance level when using the AG model.

We observe how close the parameter estimates and corresponding standard errors are for the WLW and EA minimal models. This is also seen when comparing the PWP calendar time and the EA Perfect models. This points to how the differences in models may be attributed to the EA processes.

Concluding Remarks

This article has discussed a specific form of multivariate lifetime data termed *recurrent event data*. The nature of this data requires modeling strategies to incorporate several challenging aspects. Of particular consideration is the correlation of within subject event-of-interest calendar times. A further complication is the fact that many studies have right-censored data. Four general classes of models were described that approach modeling of this data in unique ways. The bladder tumor data of Byar [5] was modeled using the different models presented in the section titled “General Classes of Models” for illustrative purposes.

Many experiments yield recurrent event data along with other data structures that were not formally discussed in this article. Often, recurrent event data is coupled with another event of interest termed a *terminal event*. The appropriate joint modeling of

the recurrent event process and the terminal event in the presence of right censoring is an important statistical challenge. The right censoring in this article was assumed to be independent and noninformative. Dependent and informative censoring are also found in many studies. These are just some of the interesting aspects that need to be addressed when studying recurrent event data.

RUSSELL S. STOCKER

Reinsurance

The Role of Reinsurance for Direct Insurers

Most individuals and organizations prefer to transfer some of the risks they stand to another entity, paying a certain agreed price. Insurance companies are no exception.

Under a contract of insurance, the insurer promises to indemnify the policyholder on the occurrence of an uncertain specified event. The policyholder agrees to pay the premium. The very same thing happens in reinsurance contracts.

Reinsurance is a form of insurance, but it has many important distinctive features. These differences result from the fact that it is *insurance for insurers*. Reinsurance contracts are celebrated between a direct *insurer* and a *reinsurer*, traditionally, “on the basis of utmost good faith”, with the purpose of transferring to the latter part of the risks assumed by the former, in its business. They are a vital instrument to the management of risk and capital. Reinsurers have contractual obligations only to direct insurers, not to policyholders.

Before reinsurance widespread, insurance companies used to constrain their acceptances only to amounts they could bear. When a risk was too large for an insurer to take alone (*see Large Insurance Losses Distributions; Ruin Probabilities: Computational Aspects*), coinsurance was practiced and each one of the direct underwriters would take a share. The first specialized company, the Kölnische Rück, was founded in the nineteenth century, after a catastrophic fire devastated Hamburg, in 1842.

Every insurer recurrently faces the same dilemma: to accept business that can induce a severe result on its claims costs, or to reject it and take the consequences of losing place to other insurers – and the smaller the company, the greater the constraints on the risks it can accept. The problematic risks are those carrying either the possible occurrence of very large individual losses or the possible accumulation of losses from one single event – normally because individual risks are not mutually independent. An insurance portfolio has to include numerous similar and independent risks to be considered balanced, so that the central limit theorem applies. Unfortunately, that is often not the case, and some extra loadings are

needed for claims fluctuations, but the market limits the size of the premiums.

The above are the main causes why reinsurance is required. Although nonlife business predominates (many life policies have small insurance risk), its benefits apply to both life and nonlife insurance and can be summarized as follows (*cf.* [1, 2]):

- To give protection against large individual losses and accumulations of losses that may endanger the direct insurer’s survival. By covering large sums insured and highly exposed risks, relative to income and reserves, the direct insurer intends to reduce the probability of ruin.
- To improve the balance of the portfolio and to stabilize underwriting results. By assuming a part of the risk of random fluctuations of small and medium size claims, reinsurance limits the instability of the annual aggregate claims.
- To aid insurers meet their solvency requirements and to provide them with additional underwriting capacity to accept individual risks and types of business otherwise unbearable (and to spread their overheads). Without reinsurance the potential market would be very limited to the majority of the underwriters and some risks would possibly not be insurable.
- To allow direct insurers to free themselves from risks that they do not want to stand alone or which they would even prefer to avoid. The flexibility in respect of the acceptable risks for the amount of capital available is increased.
- To guarantee liquidity and income, by means of financial reinsurance (also known as *finite risk* or *capital-motivated reinsurance*). It is transacted mainly to accomplish financial purposes and combines risk transfer with elements of risk finance. Financial reinsurance helps direct insurers to deal with difficult capital-planning problems and in the financing of acquisitions. More efficient use of capital and better returns on investments are obtained.
- To advise on the planning of reinsurance programmes and on the handling of very large losses – the reinsurer usually reserves the right to participate in the negotiations, contributing to an efficient adjustment of the claims.
- To offer many kinds of other services, fundamental in particular, to new companies in developing countries that lack experience and have

not enough information to rate risks and propose reasonable prices. As reinsurers collect data all over the world, they are able to help in the assessment of special and unusual risks, to give consultation in loss prevention and capital investment, to provide loss adjustment support, to perform actuarial work, to assist in the development and pricing of new products, to find cooperation associates, and even to recruit and train personnel.

Outside the field of reinsurance protection are the issues of inadequate pricing, uncontrolled costs, and bad investment policy. Reinsurance cover does not prevent direct insurers from suffering the consequences of their failures; in some cases they may continue to be very limited in the risks they can accept.

Looking from the reinsurers' perspective, they have to supply the cover demanded by their clientele and at the same time they must structure and preserve their own portfolio, risks being in line with the existing capital. This is accomplished by dispersing activities geographically and throughout the classes of business. A reinsurer may also reinsure risks it has accepted, by means of a retrocession contract. The ceding reinsurer is then the retrocedent and the other one is the retrocessionaire.

Reinsurance Forms

All reinsurances can be classified into two types: proportional and nonproportional. In the last years alternative risk transfer (ART) techniques have appeared, e.g., life and no life finite (*see Nonlife Loss Reserving*) risk reinsurance and property/casualty multiyear, multirisk, reinsurance, which are extensions of the conventional types.

Proportional reinsurance, quota share, and surplus, were the first to appear, developing from coinsurance. In this type of reinsurance, cessions are linked to the sums insured and the direct insurer and the reinsurer share premiums and losses at a contractually defined ratio. The reinsurer accepts a fixed share of the liabilities assumed by the cedent under the original contract, and receives the same proportion of the original premium, minus a commission. This commission, used to compensate the insurer for expenses met for the benefit of both, is usually defined as a percentage of the ceded premium.

Under a *quota share*, a fixed proportion of every risk accepted by the primary insurer is ceded to the

reinsurer. This proportion, *the quota*, establishes how premiums and losses are distributed between them. The pros of this kind of reinsurance are its simplicity, the low cost administration, and a certain identity between insurer and reinsurer. The main disadvantage is that quota share does not help to balance the portfolio: by reinsuring the same proportion of all risks, the relative variability and the incurred loss ratio on the retained portfolio are not reduced; it can neither limit adequately the threat of peak risks nor provide enough protection against the accumulation of losses. Since all the underwritten risks are covered, the reinsurer gets a share of the premium for policies that really do not need to be reinsured. In spite of this, quota share is often an appropriate part of the reinsurance programme, particularly when the company is entering a new market.

Surplus reinsurance, possibly the most common form of reinsurance, is also proportional, but the reinsurer does not participate in all the risks. The direct insurer retains every risk up to a certain amount, the *retention*, and the reinsurer is obliged to accept only the surplus, that is to say, the amounts accepted by the insurer above that retention. When the sum insured is below the retention, the insurer retains the entire risk. For each reinsured risk, the ratio between the retained and the ceded amounts determines how the premiums and losses are distributed to them. The ceding company can choose different retention limits directly related to the different degrees of exposition of the reinsured risks, and there is an upper limit to the reinsurer's obligation for each of them. This limit is usually defined as a certain multiple of the direct insurer's retention, known as *lines*. The cover is split into several surpluses, when it is more easily placed that way. When the sum insured exceeds the surplus, the direct insurer must either take the rest or plan additional suitable reinsurance cover. Surplus reinsurance has the merit of balancing the cedent's portfolio. By reducing the range of possible retained losses and the relative variability of costs, it also limits the highest retained exposures and allows adjusting the amount of risk. Like quota share, surplus reinsurance gives no effective protection against the accumulation of losses.

Nonproportional reinsurance, excess of loss and stop loss, won popularity in the last decades. Cessions are no longer linked to the sums insured, but to the losses, and there is not a predetermined ratio for dividing premiums and losses between insurer

and reinsurer. The share of losses paid by each one depends on the amount of the loss incurred. There is an amount up to which the direct insurer pays all losses – the deductible, net retention, excess point, or priority – and the reinsurer pays all losses above it, also up to a defined cover limit. The contract forces the reinsurer to pay only when the reinsured portfolio or risk incurs a loss that exceeds the deductible. The difficulty is to set premiums that are fair to both parties. In rating the price, the reinsurer tries to get an adequate part of the primary premium, considering the loss experience of past years (experience rating) or, if events are rare, the losses to be expected from that sort of risk (exposure rating, normally based on other available information and expert opinion).

Excess of loss (XL) can be contracted under a risk basis (per risk XL) or under an occurrence basis (per event XL). Per risk XL protects against possible large losses produced by *one policy* and the reinsurer pays any loss in excess of the deductible. Per event XL protects against an accumulation of individual losses due to *a single event* and the reinsurer pays when the deductible is exceeded by the aggregate loss from any one occurrence.

When the deductible is low enough so that it is expected that some claims will activate the contract every year, the excess of loss is named working excess of loss (WXL) cover. Catastrophe excess of loss (CatXL) is defined per event and it is used in property reinsurance to protect direct insurers against accumulation of losses due to catastrophic occurrences (earthquakes, floods, etc). A clash cover, sometimes referred to as *unknown accumulation cover*, is an excess of loss that protects against losses due to unknown accumulations (e.g., the exposure to a larger loss than anticipated in such an occurrence).

XL reinsurance is very efficient to stabilize the results of the primary insurer, by reducing its exposures on individual risks, and can also be used to deal with the problem of accumulations and catastrophe risks. On the other side, some reinsurers do not accept contracts with relatively low retentions, which may produce numerous claims, and XL cover has often to be organized in layers, thus increasing the costs. There are variations of XL covers especially devoted to the largest claims, for example, ECOMOR reinsurance (*excédent du coût moyen relatif*).

Stop loss covers are intended to protect against fluctuations in annual loss experience, in a certain

class of business: the reinsurer pays if the *aggregate losses* for a year, net of other reinsurance covers, exceed the agreed deductible and is not relevant whether it is exceeded by one single large loss or an accumulation of small- and medium-sized losses. The deductible, now expressed as a function of the aggregate net losses, is settled either as a monetary limit (stop loss) or in terms of a proportion of premium income (XL ratio). Only stop loss reinsurance has the virtue to offer simultaneous protection against increases in the severity and the frequency of losses. Administration costs are lower, but premium rating poses important practical problems. The reinsurers always limit their responsibility and the loading they charge reduces the reserves of the direct insurers. They are often reluctant to underwrite these kinds of contracts because of the large amount of risk transferred – all the losses, great and small, determine their liability – in contrast to their limited means of influencing the exposure. There is a danger of the cedent manipulating the needed information, particularly when the business is more internationalized.

The *aggregate XL* is very similar to stop loss, except that only the losses exceeding a certain amount are considered when calculating the company's annual claims burden.

The term *umbrella cover* is used when several classes of business are protected by combining the contracts of the different classes into one reinsurance contract.

Placing Reinsurance

Both types of reinsurance, proportional and nonproportional, may be either facultative or obligatory, the two basic methods of placing reinsurance.

The *facultative method* was the first to be used, when reinsurance was mainly the mutual placing of individual risks between primary insurers. The word facultative means that the deal is optional: neither is the primary insurer obliged to offer the business nor is the reinsurer obliged to accept it. Like in direct insurance, a reinsurer offered a risk can examine it and decide whether or not to accept it. The facultative method has lost significance owing to the high administration costs and the inherent inadequacy when the direct insurer has to take, without delay, a risk in excess of its retention. It is used mostly in two situations: when the insurer has exhausted its

retention and the capacity provided by the obligatory reinsurance, but additional reinsurance is still needed, and when it underwrote risks that are not included in the existing reinsurance covers and need to be individually reinsured.

In *obligatory* (or *treaty*) *reinsurance* the direct insurer is obliged to cede and the reinsurer is obliged to accept an agreed share of the risks defined in the reinsurance treaty. A treaty is a contract between a direct insurer and one or more reinsurers, where the insurer agrees to cede certain of the written risks and the reinsurer agrees to reinsure them. The terms of the treaty stipulate the risks covered and the limits of the reinsurer's liability. In obligatory reinsurance, entire and precisely defined portfolios are ceded. The reinsurer neither can refuse to provide insurance protection for an individual risk falling within the scope of the treaty, nor can the direct insurer decide not to cede a risk to the reinsurer. Thus, once a treaty has been concluded, a direct insurer (or a reinsurer, under a retrocession treaty) can obtain reinsurance automatically for risks accepted and covered by that treaty. The automatic character of treaties, normally set annually, makes obligatory reinsurance less expensive than facultative.

Facultative/obligatory (or *open cover*) arrangements are similar to treaties, with the important difference that the ceding company decides which of the covered risks are in fact reinsured. It is used mostly when the sum insured exceeds the surplus and the direct insurer must either take the rest or plan additional suitable reinsurance cover. Facultative/obligatory reinsurance gives the ability to reinsure immediately the remaining surplus falling within the scope of the arrangement and therefore to accept without delay those large risks that the restrictions in the reinsurance treaties would not allow. *Obligatory/facultative* contracts function in the opposite way.

The Design of Reinsurance Programmes

When designing a reinsurance programme, somehow, there is an attempt to decide optimally on the type of reinsurance and on how much to reinsure, but what is meant by "optimal" depends on many factors and on the significance given to each of them: the current and future business models and resultant loss exposures, the financial strength and risk aversion, the market

conditions and opportunities. Altogether, they make of each company a single case, requiring a distinct reinsurance programme.

Gerathewohl *et al.* states that "... the 'ideal' type of reinsurance applicable in all cases does not exist" [3, p. 124], and the previous paragraphs pointed out that there is no type of reinsurance which is able to protect the primary insurers against *all* the causes; why then is reinsurance required?

Following the pioneer works of de Finetti and Borch, there are many theoretical results [4] in favor of this or that type of reinsurance, depending on the optimality criteria and the premium principle that have been chosen.

The main reason why the market practices show only a weak adherence to these theoretical results is the fact that nearly all the models assume that the premium principle is independent of the particular type of reinsurance under consideration. For instance, in Borch's famous result, proving that stop loss is the optimal form of reinsurance – in the sense that, for a fixed net reinsurance premium, it gives the smallest variance of the net retention – it is assumed that the loading coefficient on the net premium is not different from that in a conventional quota treaty. This is not a reasonable assumption and Borch himself said later [5, pp. 293–295]:

I do not consider this a particularly interesting result ... Do we really expect a reinsurer to offer a stop loss contract and a conventional quota treaty with the same loading on the net premium? If the reinsurer is worried about the variance in the portfolio he accepts, he will prefer to sell the quota contract, and we should expect him to demand a higher compensation for the stop loss contract.

Yet, the exceptions to this somewhat unrealistic approach are very unusual (see a few in [6]).

An example of the current practice is provided by Schmutz [7] in the form of a "pragmatic approach" for the designing of reinsurance programmes. The proposed method supplies a set of empirical rules that are exclusively applicable to property reinsurance, a branch where typically all forms and types of contracts are used. For instance, it is common to start by contracting a facultative proportional arrangement, to reduce the largest risks, followed by a surplus treaty, to homogenize the retained portfolio, and then a quota share on the retention of the surplus treaty and a WXL, to protect against major losses. As natural

hazards may occur, in some cases it will be wise to protect the per risk retention with a CatXL treaty.

As Gerathewohl *et al.* [3] explain, although the design of a reinsurance programme is essentially a management decision, there are various standards for determining the retentions, for instance, the premiums and shareholders' funds criteria and the claims ratios and fluctuations criteria. In practice, the variance is the most used measure for these fluctuations. Naturally, the final decision has always to balance the level of the direct insurer's retention with the desired level of business profitability.

Relative Risk

Risk is often quantified by calculating risk ratios. The presentation of risk influences its perception. For example, one might be worried to hear that one’s lifestyle doubled the risk of a serious disease compared to some other way of life. However, the statement that the risk had increased from one in a million to two in a million might be less worrying. In the first case, it is a *relative* risk that is presented, in the second an *absolute* risk.

The relative risk measures how the probability of an event, typically of getting a disease, varies between two categories, namely, a group that is exposed to a risk factor and one that is not. The specific definitions are most easily understood in terms of a 2×2 table of exposure by disease as shown in Table 1. Therein, N denotes the population size and a, b, c , and d the absolute frequencies of the respective combinations of the levels of the risk factor (exposed or not exposed) and the disease factor (present or absent). The (absolute) risk of the disease within a subpopulation is defined as the proportion of the subgroup that have the disease, i.e., $r(\text{disease present} | \text{exposed group}) = a / (a + b)$ and $r(\text{disease present} | \text{nonexposed group}) = c / (c + d)$. Then the relative risk ratio (RRR), of disease comparing the exposed with the nonexposed subpopulation is given by the ratio $RRR = \frac{a/(a+b)}{c/(c+d)}$.

For example, a relative risk of coronary heart disease, comparing obese people with nonobese people, of two would be interpreted as a doubling of the risk of heart disease when putting on weight. Similarly, a relative risk of contracting measles comparing vaccinated children with nonvaccinated children of 0.5 would be interpreted as a protective effect.

While the relative risk is a popular choice for expressing the effect of exposure on disease, there are a number of other indices that can be used for

this purpose. They divide into measures that contrast event probabilities, for example, *absolute risk reduction* (see **Absolute Risk Reduction**), attributable fraction (see **Attributable Fraction and Probability of Causation**), and indices that contrast other measures of chance, for example, odds ratios (see **Odds and Odds Ratio**).

It is important to use an appropriate study design when estimating the relative risk in the population from a sample. Cross-sectional studies typically fix the sample size N and in *cohort studies* (see **Cohort Studies**), the sizes of the cohorts of exposed and non-exposed subjects (the row totals in Table 1) are under the control of the investigator. Both these restrictions allow the risk of disease within the exposure groups and hence the RRR to be estimated. In contrast, in a *case-control study* (see **Case-Control Studies**), the number of subjects with the disease and the number of subjects without the disease (the column totals in Table 1) are chosen by the investigator, making it impossible to estimate disease risks from the sample data. However, when the disease is rare, it is possible to use the odds ratio as an approximation (see **Odds and Odds Ratio**).

Reliability Data

The need for quantitative reliability assessment (*see* **Imprecise Reliability; Mathematics of Risk and Reliability; A Select History; Near-Miss Management; A Participative Approach to Improving System Reliability**) in industrial risk management has been dictated by major hazards legislation (*see* **Economic Criteria for Setting Environmental Standards**), concern for protection of the environment, and the safety of personnel working in or near to industrial installations. At a meeting of experts from all sectors of industry organized jointly by The Engineering and Physical Sciences Research Council and the Institution of Mechanical Engineers in 1996, the lack of good quality reliability and maintenance data was a common complaint. Ten years later, the situation is little different due primarily to uncertainties of reliability data requirements in different areas of reliability analysis, the different types of data and methods for their collection and analysis. However, a variety of reliability data sources are now featured on the Internet.

Basically, reliability data (*see* **Reliability Demonstration; Lifetime Models and Risk Assessment; Reliability Integrated Engineering Using Physics of Failure**) are required during the three main phases of an engineering system's lifetime:

1. in the design phase, as input to the models developed to predict the reliability, availability, and maintainability of safety and production systems;
2. prior to manufacture and operation, to support the preparation of reliability specifications, quality control procedures, test programs, and inspection and maintenance planning;
3. during operation, to monitor the efficacy of reliability performance and identify areas where hazards and production losses can be reduced by application of reliability based techniques such as reliability centered maintenance and risk-based inspection.

Generic statistics of equipment failure characteristics from in-house and published sources generally form the database for the first two areas. In-service experience provides more detailed, system-specific failure information suitable for ongoing reliability monitoring and feedback into the generic database.

The principal types of data required are known respectively as generic reliability data (*see* **Probabilistic Risk Assessment**) and in-service reliability data. In both cases, it is important to ensure that reliability data are based on clear definitions, and collected and analyzed to well-defined procedures. Vague descriptions of equipment, engineering, and functional attributes, system boundaries, and failure descriptors can lead to uncertainties in the results. The objective of this article is therefore to cover the basics of reliability data collection and analysis. Other publications cover the subject in more detail and include more detailed methodologies for generic and in-service reliability data analysis, its collection, and quality control [1–4].

Generic Reliability Data

The reliability assessment of an engineering system requires a variety of different types of generic data. A database of relevant reliability information is required related to the study objective – say, to predict whether the system will meet some previously defined reliability target. This could be the probability of failure on demand of a safety system or the expected steady-state availability of a manufacturing system. In all cases, the study aims to identify the relative importance of the different pieces of equipment in the system, the critical failure modes, and the distribution of hazards and/or downtime with respect to the different subsystems and equipment.

Typical data required are as follows:

- overall equipment failure rates
- principal failure modes and proportions
- common cause failure rates
- human error rates
- spurious trip rates
- fail-to-start probabilities
- active repair and waiting times.

Although most of these data classes are identical for both safety and availability studies, the emphasis is different. In safety studies, the principal objective is to identify the potentially dangerous equipment and component failure modes, whereas in availability studies, the main focus is on the equipment and failure modes that cause forced outage or production loss.

Generic reliability data can be obtained from a variety of sources. These include in-house information collected from operating plant, data tabulated in reliability data handbooks, and the variety of reliability data now available *via* the Internet. There is a general reluctance on the part of most organizations to publish reliability data since it is often viewed as commercially sensitive. In 1993, therefore, the IMechE Mechanical Reliability Committee's Data Acquisition Working Party carried out a review of existing generic reliability data sources. The results were published by the IMechE and reviewed in 1993 [5]. The 20 generic data sources are shown here in Table 1. Sources of electronic component and equipment data are also published from time to time by the Rome Air Development Center, for example [6].

As one progresses from data in the public domain to in-house sources, the extent of the information available increases and uncertainties diminish. The relevant information should now be assembled on a project database before more detail analysis is applied to determine the best estimates of equipment failure rates in the critical failure modes.

Determining best estimates from the very diverse and frequently small data available can be a daunting task. Generic reliability data available in the public domain has significant limitations and is frequently confined to a single figure of failure rate for a specific type of equipment. Besides the effect of different physical and environmental stresses, uncertainties arise from the imprecision of the item description and the operational, maintenance, and industrial conditions associated with the systems from which the generic failure rate was derived. Where there are a large number of failure rates available for a specific type of equipment, the range is likely to be very large. For example, Figure 1 illustrates the lognormal distribution of circuit breaker failure rates listed in one generic database which shows a factor of approximately 100 between highest and lowest estimates. This is quite typical for a wide range of equipment in manufacture, power production, transport, and military systems.

To derive a best-estimate failure rate (*see Repair, Inspection, and Replacement Models*) from such diverse information requires a structured approach and the application of engineering judgment to

initially define a reference point within the distribution of generic failure rates. The reference-point failure rate is generally assumed to be the median of the generic failure rate distribution and to reflect "average industrial conditions", since 50% of the observed failure rates will be above and 50% below the reference point. This is termed the *base failure rate* (λ_b). For circuit breakers, λ_b indicated by the data in Figure 1, is 4 failures/ 10^6 h.

The second step is to scale this base failure rate to reflect the different conditions of the system being assessed and the equipment failure mode(s) that could trigger system failure. A common model employed for electromechanical equipment is given by

$$\lambda_{XA} = \lambda_b \cdot \alpha_A \Pi k_i \quad (1)$$

where λ_{XA} is the estimated failure rate for equipment X in failure mode A, λ_b is the base generic failure rate, α_A is the proportion of all failures in failure mode A, and Πk_i is the product of the different stress factors.

A subjective methodology for estimating stress factors based on the differences between the "average industrial conditions" associated with the reference-point failure rate (λ_b) and the system being assessed is the DOE (Design, Operation, Environment) model. Scores for design, operation, and environment stress attributes are allocated on the scale -1 to $+1$.

Stress	Low	Average	High
Score (z)	-1	0	$+1$

Fractions within and outside the range are allowed, and k factors are calculated from the expression

$$k = e^z \quad (2)$$

where z is the estimated score for the design, operation, and environment attributes of the system. Assuming a circuit breaker is installed in the electrical distribution system of a petrochemical plant located on a UK estuary, the k factors would perhaps be

Design z score say, $+0.25$ – (air-operated, high voltage circuit breaker)

Operation z score say, 0 – (normal operation, regularly tested and maintained)

Table 1 Principal Reliability Data Sources

Data source	Title	Publisher and date
1. CCPS	<i>Guidelines for process equipment reliability</i>	American Institute of Chemical Engineers, 1990
2. Davenport and Warwick	A further survey of pressure vessels in the UK 1983–1988	AEA Technology – Safety and Reliability Directorate, 1991
3. DEFSTAN 0041, Part 3	<i>MOD practices and procedures for reliability and maintainability, Part 3, Reliability prediction</i>	Ministry of Defence, 1983
4. R. F. de la Mare	Pipeline reliability; report 80-0572	Det Norske Veritas/Bradford University, 1980
5. Dexter and Perkins	Component failure rate data with potential applicability to a nuclear fuel reprocessing plant, report DP-1633	EI Du Pont de Nemours and Company, USA, 1982
6. EIREDA	<i>European industry reliability data handbook</i> , Vol. 1, <i>Electrical power plants</i>	EUROSTAT, Paris, 1991
7. ENI Data Book	<i>ENI reliability data bank – component reliability handbook</i>	Ente Nazionale Indrocarburi (ENI), Milan, 1982
8. Green and Bourne	<i>Reliability technology</i>	Wiley Interscience, London, 1972
9. IAEA TECDOC 478	<i>Component reliability data for use in probabilistic safety assessment</i>	International Atomic Energy Agency, Vienna, 1988
10. IEEE Std 500-1984	<i>IEEE guide to the collection and presentation of electrical, electronic sensing component and mechanical equipment reliability data for nuclear power generating stations</i>	Institution of Electrical and Electronic Engineers, New York, 1983
11. F. P. Lees	<i>Loss prevention in the process industries</i>	Butterworth, London 1980
12. MIL-HDBK 217E	<i>Military handbook – reliability prediction of electronic equipment</i> , Issue E	US Department of Defense, 1986
13. NPRD-3	<i>Non-electronic component reliability data handbook – NPRD-3</i>	Reliability Analysis Centre, RADC, New York, 1985
14. OREDA 84	<i>Offshore reliability data (OREDA) handbook</i>	OREDA, Hovik, Norway, 1984
15. OREDA 92	<i>Offshore reliability data</i> , 2nd edition	DnV Technica, Norway, 1992
16. RKS/SKI 85-25	<i>Reliability data book for components in Swedish nuclear power plants</i>	RKS – Nuclear Safety Board of the Swedish Utilities and SKI – Swedish Nuclear Power Inspectorate, 1987
17. H. A. Rothbart	<i>Mechanical design and systems handbook</i>	McGraw-Hill, 1964
18. D. J. Smith	<i>Reliability and maintainability in perspective</i>	Macmillan, London, 1985
19. Smith and Warwick	A survey of defects in pressure vessels in the UK (1962–1978) and its relevance to primary circuits, report SRD R203	AEA Technology – Safety and Reliability Directorate, 1981
